

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

### Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

### About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

THE  
SCIENCE AND ART  
OF  
SURGERY.

*A Treatise on Surgical Injuries, Diseases, and Operations.*

BY

SIR JOHN ERIC ERICHSEN, BT., F.R.S., LL.D. (EDIN.)

HON. M.CH. R. UNIV. IRELAND, AND F.R.C.S. (IRELAND).

SURGEON EXTRAORDINARY TO HER MAJESTY THE QUEEN.

PRESIDENT OF UNIVERSITY COLLEGE, LONDON.

FELLOW AND EX-PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND.

EMERITUS PROFESSOR OF SURGERY, UNIVERSITY COLLEGE. CONSULTING SURGEON, UNIVERSITY COLLEGE HOSPITAL.

HONORARY MEMBER ROYAL ACADEMY OF MEDICINE OF BELGIUM AND OF NEW YORK—CORRESPONDING MEMBER OF IMPERIAL AND ROYAL SOCIETY OF PHYSICIANS, VIENNA—HONORARY MEMBER OF AMERICAN SURGICAL ASSOCIATION—OF SOCIETY OF MEDICAL AND NATURAL SCIENCE, BRUSSELS—OF ACCADEMIA DE' QUIRITI, ROME, ETC., ETC.

TENTH EDITION.

REVISED BY THE LATE

MARCUS BECK, M.S. & M.B. (LOND.), F.R.C.S.

SURGEON TO UNIVERSITY COLLEGE HOSPITAL; AND PROFESSOR OF SURGERY IN UNIVERSITY COLLEGE, LONDON.

AND BY

RAYMOND JOHNSON, M.B. & B.S. (LOND.), F.R.C.S.

ASSISTANT SURGEON TO UNIVERSITY COLLEGE HOSPITAL AND TO THE VICTORIA HOSPITAL FOR CHILDREN; HUNTERIAN PROFESSOR ROYAL COLLEGE OF SURGEONS OF ENGLAND, 1894.

*Illustrated by nearly One Thousand Engravings on Wood.*

VOL. II.

LONDON:

LONGMANS, GREEN, AND CO.

1895.

# CONTENTS OF THE SECOND VOLUME.

## DIVISION THIRD.

### SURGICAL DISEASES.

(CONTINUED.)

#### CHAPTER XXXVII.—SURGICAL DISEASES OF THE SKIN AND ITS APPENDAGES.

	PAGE
DISEASES OF THE APPENDAGES OF THE SKIN—Diseases of the Nails—Atrophy—Hypertrophy of Toe-Nail—Onychia—Simple—Syphilitic—Ingrowing of the Nail . . . . .	1—8
DISEASES OF THE SKIN—Lupus Erythematosus and Lupus Vulgaris—Symptoms—Causes—Prognosis—Diagnosis—Treatment—Scrofuloderma—Carcinoma of the Skin—Primary Carcinoma—Squamous Carcinoma or Epithelioma—Rodent Ulcer—Symptoms—Diagnosis—Pathology—Treatment—Secondary Carcinoma of the Skin—Sarcoma of the Skin—Melanotic and Alveolar Sarcoma—Treatment—Simple Tumours of the Skin—Fibroma—True Keloid—False Keloid—Morphœa—Osteomata—Adenomata—Moles—Papillomata, or Warts—Corns—Suppurating Corn—"Black Corn"—Perforating Ulcer of Foot . . . . .	3—20

#### CHAPTER XXXVIII.—DISEASES OF THE NERVOUS SYSTEM.

NEURITIS—Symptoms—Treatment . . . . .	21—22
SCIATICA—Symptoms—Diagnosis—Treatment—Acupuncture—Stretching the Sciatic Nerve . . . . .	22—24
NEURALGIA—Symptoms—Situations—Causes—Diagnosis—Treatment—Stretching of Affected Nerve—Section of Affected Nerve—Facial or Trigeminal Neuralgia . . . . .	24—33
MUSCULAR TIC . . . . .	33—34
TRAUMATIC PARALYSIS—Rheumatic Paralysis, or Paralysis from Exposure to Cold—Treatment . . . . .	34—35
NEUROMA—Structure—Traumatic Neuroma—Treatment . . . . .	35—37

#### CHAPTER XXXIX.—DISEASES OF THE LYMPHATIC SYSTEM.

INFLAMMATION OF THE LYMPHATIC VESSELS—Lymphangitis, or Angioloecuditis—Causes—Morbid Anatomy—Symptoms—Results—Diagnosis—Treatment . . . . .	38—40
VARIX OF THE LYMPHATIC VESSELS—Occurrence—Treatment . . . . .	40
ELEPHANTIASIS ARABUM—Pathology—Treatment . . . . .	40—43
LYMPHADENITIS, OR INFLAMMATION OF LYMPHATIC GLANDS—Acute: Pathological Anatomy—Symptoms—Treatment—Chronic.—TUBERCULOUS DISEASE: Symptoms—Pathological Anatomy—Diagnosis—Treatment . . . . .	44—49
LYMPHADENOMA—Removal . . . . .	49—50

## CHAPTER XL.—DISEASES OF VEINS.

VENOUS THROMBOSIS—Causes—Process of—Fate of the Thrombus—Effects—Symptoms—Treatment . . . . .	51—57
PHLEBITIS—Causes—Pathological Anatomy—Symptoms—Treatment . . . . .	57—60
VARICOSE VEINS, OR VARIX—Definition—Causes—Locality—Morbidity—Anatomy—Appearances and Symptoms—Progress and Effects—Treatment—Obliteration of Varicose Veins . . . . .	61—66

## CHAPTER XLI.—ANEURISM BY ANASTOMOSIS, AND NÆVUS—HÆMORRHAGIC DIATHESIS.

ANEURISM BY ANASTOMOSIS—Nature—Diagnosis—Treatment . . . . .	67—68
NÆVUS—Capillary—Venous or Cavernous—Prognosis—Treatment—Operations: Cutaneous Nævus—Excision—Cautery—Caustics—Subcutaneous and Mixed Nævi: Excision—Galvano-puncture—Ligature.—NÆVI IN SPECIAL SITUATIONS—Scalp—Fontanelle—Face—Eyelids—Nose—Cheeks—Lips—Tongue—Penis—Vulva—Nævoid Lipoma . . . . .	69—81
HÆMORRHAGIC DIATHESIS, OR HÆMOPHILIA—Causes—Pathology—Treatment . . . . .	81—84

## CHAPTER XLII.—DISEASES OF ARTERIES.

ACUTE INFLAMMATION OF ARTERIES—Acute Arteritis—Traumatic Arteritis—Arteritis by Extension—Embolie Arteritis—Acute Endarteritis.—CHRONIC INFLAMMATION OF ARTERIES—Arteritis Deformans or Atheroma—Nature and Causes—Effects—Arteritis Obliterans—Endarteritis Proliferans . . . . .	85—95
PRIMARY DEGENERATIONS OF ARTERIES—Fatty Degeneration—Albumenoid—Calcification—Ossification—Effects of Disease—Ulceration—Spontaneous Rupture—Contraction and Occlusion . . . . .	95—100

## CHAPTER XLIII.—ANEURISM.

ANEURISM defined—Causes—Classification—Fusiform or Tubular Aneurism—Sacculated Aneurism—True—False—Dissecting Aneurism—Structure of Sacculated Aneurism—Pressure—Effects—Number—Duration—Symptoms of External Circumscribed Aneurism: of Diffuse Aneurism—Diagnosis—Terminations—Spontaneous Cure—Causes of Death from Aneurism—Treatment: Constitutional or Medical—Local . . . . .	101—119
SURGICAL TREATMENT OF ANEURISM.—LIGATURE.—Situation—Ligature on both Sides of Sac—Ligature on Cardiac side of Aneurism—Distal Ligature—Indications and Contra-indications of Ligature—Accidents after Ligature—Secondary Hæmorrhage—Continuance or Return of Pulsation—Secondary Aneurism—Treatment of Recurrent Pulsation—Suppuration and Sloughing of Sac—Treatment—Gangrene—Causes—Treatment.—COMPRESSION BY INSTRUMENTS—Principle—Circumstances influencing Success—Application of Compressor—Under Anæsthetics—Effects—Duration of Treatment—Applicability—Digital Compression—Esmarch's Elastic Bandage—Flexion—Manipulation—Galvano-puncture—Injection with Perchloride of Iron—Hypodermic Injection of Ergotin—Introduction of Foreign Bodies—Acupuncture . . . . .	119—152
ARTERIO-VEINOSUS ANEURISMS. . . . .	152

CHAPTER XLIV.—ANEURISMS OF THE THORAX, HEAD AND  
NECK, AND UPPER EXTREMITY.

THORACIC AORTA—Symptoms—Auscultatory Signs—Pressure-effects—Pulsation and Tumour—Treatment . . . . .	153—161
INNOMINATE ARTERY—Symptoms—Pressure-effects—Prognosis—Diagnosis—Treatment—Ligature of Subclavian only—Of Carotid only—Of Carotid and Subclavian—General Remarks on the Operation . . . . .	161—168
CAROTID ARTERY—Aneurismal Varix of Carotid Artery and Jugular Vein—Spontaneous Aneurism of Carotid—Symptoms—Diagnosis—Treatment—Digital Compression—Ligature of Common Carotid—Effects on Brain—Table of Cases of Ligature of Carotid—Ligature of Carotid on Distal Side . . . . .	168—178
EXTERNAL CAROTID ARTERY—Ligature. . . . .	178—179
INTERNAL CAROTID ARTERY—Extracranial Aneurism—Treatment. . . . .	179—180
INTRACRANIAL ANEURISM—Causes—Pathology—Pressure-effects—Symptoms—Causes of Death—Treatment . . . . .	180—185
INTRAORBITAL ANEURISM—Erroneous Opinion regarding—Causes—Symptoms—Pathology—Diagnosis—Prognosis—Treatment . . . . .	185—188
SUBCLAVIAN ARTERY—Symptoms—Diagnosis—Results—Treatment—Ligature of the Innominate Artery—Table of Cases—Ligature of First Part of Right Subclavian—Table of Cases—Ligature of First Part of Left Subclavian—Of Third Part of Subclavian—Distal Ligature of Subclavian beyond the Scalenii—Amputation at Shoulder-joint, and Distal Ligature—Ligature of Vertebral Artery . . . . .	188—199
AXILLARY ARTERY—Symptoms—Diagnosis—Treatment—Ligature of Third Part of Subclavian—Accidents during Ligature of the Third Part of the Subclavian—Ligature behind the Scalenus anticus—Results of Ligature of the Subclavian—Suppuration of the Sac—Secondary Hæmorrhage—Gangrene of Hand and Arm—Treatment of Inflamed Axillary Aneurism threatening Suppuration—Ligature of Axillary Artery . . . . .	199—215
ARM, FOREARM, AND HAND—Rarity of Spontaneous Aneurism—Treatment—Ligature of Brachial Artery—Ligature of Radial and Ulnar Arteries . . . . .	215—219

CHAPTER XLV.—ANEURISMS OF THE ABDOMEN AND LOWER  
EXTREMITIES.

ABDOMINAL AORTA AND ITS BRANCHES—Symptoms—Diagnosis—Treatment—Compression of Abdominal Aorta . . . . .	220—223
INGUINAL ANEURISM—Symptoms—Diagnosis—Treatment by Compression—Ligature of External Iliac Artery—Abernethy's Operation Modified—Cooper's Method—Results—Ligature of Common Iliac—Results—The Old Operation—Ligature of Aorta—Table of Cases—Aneurism of Internal Iliac and its Branches—Gluteal and Sciatic Aneurisms—Treatment—Ligature of Internal Iliac . . . . .	223—236
FEMORAL AND POPLITEAL ANEURISMS—Aneurism of Deep Femoral Artery—Treatment—Aneurism of Superficial Femoral and Popliteal Arteries—Symptoms—Diagnosis—Treatment—Compression—Flexion—Ligature of Common Femoral—Of Superficial Femoral—Results—Accidents attending Operation—Wound of Femoral Vein—Secondary Hæmorrhage—Gangrene—Return of Pulsation in Sac—Secondary Aneurism—Ligature of Femoral Artery in Middle of Thigh—Ligature of External Iliac in Popliteal Aneurism—Double Popliteal Aneurism—Diffused Popliteal Aneurism—Treatment—Old Operation—Amputation . . . . .	236—250
ANEURISM OF THE TIBIAL ARTERIES—Ligature of Popliteal Artery—Of Posterior Tibial—Of Anterior Tibial—Of Arteria Dorsalis Pedis—Of Peroneal Artery . . . . .	250—254

## CHAPTER XLVI.—INFLAMMATION OF BONE AND ITS EFFECTS.

<b>GENERAL PATHOLOGY OF INFLAMMATORY AFFECTIONS OF BONE—Inflammatory Processes in the Periosteum—Affecting Compact Tissue—In the Medulla of Long Bones—In the Cancellous Tissue—Tuberculous Disease . . . . .</b>	<b>255—268</b>
<b>PERIOSTITIS—Symptoms—Treatment . . . . .</b>	<b>268—269</b>
<b>CHRONIC OSTEITIS AND PERIOSTITIS—Causes—Symptoms—Treatment . . . . .</b>	<b>269—270</b>
<b>CHRONIC ABSCESS OF BONE—Causes—Symptoms—Treatment . . . . .</b>	<b>270—273</b>
<b>DIFFUSE SEPTIC OSTEOMYELITIS—Symptoms—Treatment . . . . .</b>	<b>274—277</b>
<b>ACUTE NECROSIS—Symptoms—Pathology—Results—Diagnosis—Prognosis—Treatment . . . . .</b>	<b>277—280</b>
<b>CARIES—Definition—Causes and Varieties: Simple—Syphilitic—Tuberculous—Situation—Symptoms—Treatment—Operations on Carious Bone . . . . .</b>	<b>280—286</b>
<b>NECROSIS—Nature—Causes—Characters—Peripheral and Central—Sequestrum—Symptoms—Separation of the Dead Bone—Exfoliation—Reparative Process—Treatment—Removal of the Sequestrum—Instruments—Amputation—Resection—Syphilitic Necrosis of the Cranial Bones—Tuberculous Necrosis of Bone . . . . .</b>	<b>286—299</b>

## CHAPTER XLVII.—STRUCTURAL CHANGES IN BONE AND TUMOURS OF BONE.

<b>HYPERTROPHY—True Hypertrophy—Inflammatory Hypertrophy—Increased Length.—ATROPHY—Arrested Growth . . . . .</b>	<b>300—301</b>
<b>RICKETS—Causes—Symptoms—Progress and Prognosis—Pathology—Treatment—Combination of Rickets and Scurvy . . . . .</b>	<b>301—306</b>
<b>MOLLITIES OSSIUM: OSTEOMALACIA—Nature—Causes—Seat of the Disease—State of Urine—Symptoms—Diagnosis—Treatment . . . . .</b>	<b>306—309</b>
<b>OSTEITIS DEFORMANS—Causes—Symptoms—Pathology . . . . .</b>	<b>309—310</b>
<b>ACHROMEGALY—Causes—Symptoms—Diagnosis—Pathological Anatomy . . . . .</b>	<b>310—311</b>
<b>TUMOURS OF BONE—Exostosis: Ivory—Spongy or Cancellous—Of Ungual Phalanx of Great Toe—Chondromata or Cartilaginous Tumours—Fibroma—Cystic Tumours—Treatment—Hydatids.—SARCOMATA OF BONE.—PRIMARY MALIGNANT DISEASE—Central—Peripheral—Situations—Diagnosis—Treatment.—SECONDARY SARCOMATA.—CARCINOMA—Glandular—Squamous—Columnar.—PULSATING TUMOURS—Situation—Symptoms—Diagnosis—Treatment . . . . .</b>	<b>312—325</b>

## CHAPTER XLVIII.—DISEASES OF JOINTS.—EXCISION OF JOINTS.

<b>SYNOVITIS—Serous or Simple—Acute—Causes—Pathology—Symptoms of Acute Synovitis—Chronic Serous Synovitis—Hydrarthrosis or Droopy of Joint—Terminations—Treatment of Serous Synovitis . . . . .</b>	<b>326—330</b>
<b>ACUTE ARTHRITIS—Situations—Symptoms—Suppuration—Diagnosis—Pathology—Nature of Changes in Cartilage—Destruction of Cartilage from Synovial Disease—From Disease of Bone—Causes and Varieties—Repair—Treatment . . . . .</b>	<b>331—343</b>
<b>TUBERCULOUS DISEASE OF JOINTS—Pathological Anatomy—Primary Tubercle of the Synovial Membrane—Primary Tubercle of Bone—Symptoms—Terminations—Treatment—Arthrotomy—Erasion—Excision—Amputation . . . . .</b>	<b>343—354</b>
<b>CHRONIC RHEUMATIC ARTHRITIS—Nature—Symptoms—Causes—Diagnosis—Treatment—Chronic Rheumatoid Arthritis of Hip—Pathological Changes—Diagnosis—Chronic Rheumatoid Arthritis of Lower Jaw—Of Shoulder . . . . .</b>	<b>354—359</b>

	PAGE
<b>DISEASES OF JOINTS OF CEREBRAL OR SPINAL ORIGIN—Arthropathy of Paralyse</b>	
Limbs—Of Ataxic Patients, or Charcot's Disease . . . . .	359—361
<b>ANKYLOSIS OR STIFF JOINT—Incomplete or Fibrous Ankylosis—Complete or</b>	
Osseous Ankylosis—Treatment . . . . .	361—364
<b>LOOSE CARTILAGES IN JOINTS—Warty Condition of Synovial Membrane—Loose</b>	
Bodies—Characters—Symptoms—Diagnosis—Treatment . . . . .	364—367
<b>CYSTS IN CONNEXION WITH JOINTS . . . . .</b>	367—368
<b>NEURALGIA OF JOINTS—Symptoms—Causes—Treatment . . . . .</b>	368—369
<b>EXCISION OF JOINTS—History—Indications for Excision—Conditions of Success—</b>	
Repair after Excision—Instruments—Operation . . . . .	369—377

## CHAPTER XLIX.—DISEASES OF THE BONES AND JOINTS OF THE UPPER EXTREMITY.

<b>CLAVICLE—Excision . . . . .</b>	378—379
<b>SCAPULA—Removal of the whole Scapula—Partial Excision—Operation—Result</b>	379—382
<b>SHOULDER-JOINT—Excision for Disease—Partial Excision—Complete Excision—</b>	
Operations—Result—Excision for Compound and Comminuted Fracture . . . . .	382—387
<b>ELBOW-JOINT—Tuberculous Disease—Arthrectomy—Excision for Tuberculous</b>	
Disease—For Osseous Ankylosis—For Compound Fracture or Dislocation—	
Operation—Results . . . . .	387—395
<b>RADIUS AND ULNA—Excision of Olecranon . . . . .</b>	395—396
<b>WRIST-JOINT—Tuberculous Disease—Excision—Lister's Operation—After-Treatment</b>	
—Results . . . . .	396—400
<b>CONSERVATIVE SURGERY OF THE HAND—Excision of Fingers—Of Metacarpal</b>	
Bone . . . . .	400—402

## CHAPTER L.—DISEASES OF THE BONES AND JOINTS OF THE LOWER EXTREMITY.

<b>SACRO-ILIAC JOINT—Nature—Pathology—Symptoms—Pain—Swelling—Lameness—</b>	
Alteration in Limb—Abscess—Diagnosis—Prognosis—Treatment . . . . .	403—409
<b>PELVIC BONES . . . . .</b>	409
<b>HIP-JOINT—Pathology.—SYNOVITIS.—ACUTE ARTHRITIS—Symptoms—Result—</b>	
Treatment . . . . .	409—412
<b>TUBERCULOUS DISEASE OF THE HIP-JOINT—Pathology—Symptoms—Pain—Attitude—</b>	
Limitation of Movement—Suppuration—Sinuses—Dislocation—Ankylosis—	
Course of a Typical Case—Diagnosis—Prognosis: as concerning Life; Utility	
of Limb—Treatment: Arthrectomy—Indications for Excision—Amputation—	
Excision of the Hip-Joint—Operations—Results . . . . .	412—439
<b>ANKYLOSIS OF THE HIP—Operation for Angular Osseous Ankylosis—Cross or</b>	
Scissor-legged Deformity . . . . .	439—443
<b>FEMUR—Tuberculous Disease of the Great Trochanter—Of Neck of Femur . . . . .</b>	443
<b>KNEE-JOINT—Tuberculous Disease—Treatment—Arthrotomy—Arthrectomy—Ex-</b>	
cision—Operation—Results of Excision . . . . .	444—454
<b>PATELLA—Necrosis—Tuberculous Disease . . . . .</b>	454—455
<b>TIBIA AND FIBULA—Necrosis . . . . .</b>	455—456
<b>ANKLE-JOINT—Tuberculous Disease—Treatment—Arthrectomy—Excision . . . . .</b>	456—458
<b>TUBERCULOUS DISEASE OF THE TARSUS AND METATARSUS—Progress of Con-</b>	
servative Surgery.—ON CALCIS—Excision—Ollier's Method—History and	
Results.—ASTRAGALUS—Excision—Osteoplastic Resection of the Foot—Excision	
of Cuboid—Of Scaphoid—Of Cuneiform Bones—Excision of more than one of	
the Tarsal Bones—Metatarsal Bones—Phalanges . . . . .	458—469

CHAPTER LI.—DISEASES OF THE SPINE.

SPINA BIFIDA—Symptoms—Pathological Anatomy—Forms: Spinal Meningocele—Meningo-Myelocele—Syringo-Myelocele—Spina Bifida Occulta—Diagnosis—Prognosis—Treatment—Ligature—Excision—Injection of Sac . . . . .	470—476
TUBERCULOUS DISEASE OF THE SPINE.—CARIES.—ANGULAR CURVATURE.—POTT'S DISEASE—Causes—Pathology—Seat—Symptoms—Pleuritic Attacks—Abscess—Slow Compression of Cord in Spinal Disease—Compression Paraplegia—Symptoms—Acute Spinal Meningitis—Diagnosis—Prognosis—Treatment: Of Abscess—Of Paraplegia . . . . .	476—498
DISEASE OF THE CERVICAL SPINE—Diseases of the Atlas, Axis, and Occiput—Retro-pharyngeal Abscess—Treatment . . . . .	498—500
OTHER DISEASES OF THE SPINE—Gummata—Rheumatoid Arthritis—Tumours—Tumours in Spinal Canal . . . . .	500—501

CHAPTER LII.—DISEASES OF BURSÆ, SHEATHS OF TENDONS, AND MUSCLES.

DISEASES OF BURSÆ—Situations in which Bursæ exist—Morbid Alterations.—DISEASES OF THE BURSA PATELLÆ—Inflammation—Suppuration—Treatment—Disease of the Patella—Sloughing of the Bursa Patellæ—Enlargements—Housemaid's Knee—Treatment—Chronic Enlargement—Solid Tumours—Treatment.—DISEASES OF OTHER BURSÆ.—BUNION—Treatment . . . . .	502—510
DISEASES OF SHEATHS OF TENDONS.—ACUTE TENO-SYNOVITIS—Treatment.—CHRONIC TENO-SYNOVITIS—Symptoms—Treatment.—SIMPLE GANGLION—Treatment.—CARTILAGINOUS TUMOURS . . . . .	511—513
DISEASES OF MUSCLES—Fatty Degeneration—Ossification—Inflammatory Affections—Myositis Ossificans—Syphilitic Disease—Tumours—Treatment . . . . .	513—517

CHAPTER LIII.—DEFORMITIES.

LATERAL CURVATURE OF THE SPINE: SCOLIOSIS—Kyphosis and Lordosis—Primary Lateral Curvature—Causes—Mechanism and Pathology—Signs of Lateral Curvature—Treatment—Recumbent Position—Mechanical Contrivances—Secondary Lateral Curvature . . . . .	518—524
DEFORMITIES OF THE NECK AND LIMBS—Causes—Treatment—Tenotomy—Repair of Divided Tendons . . . . .	524—529
DEFORMITIES AFFECTING THE FACE AND NECK—Wry-Neck—Nature—Causes—Symptoms—Treatment . . . . .	529—533
DEFORMITIES OF THE ARM AND HAND—Contraction of the Arm—Straight Ankylosis—Acquired Contraction of Muscles of Forearm—Paralysis of Extensors and Supinators—Club-hand—Arthritis Deformans of Hand—Dupuytren's Contraction of the Fingers—Pathology—Diagnosis—Treatment—Contraction of Finger Backwards—Hammer Finger—Congenital Deformities of Fingers and Hand—Webbing of Fingers . . . . .	533—541
DEFORMITIES OF THE LEG AND FOOT—Genu Valgum or Knock-knee—Mode of Production—Treatment—Antiseptic Osteotomy—Genu Varum or Bow-Knee—Genu Recurvatum—Contraction of the Knee-joint—Contraction from Inflammation of Knee—Hysterical Contraction—Chronic Contraction—Contraction from Ligamentous Consolidation—Treatment—Contraction of Hamstrings—Division of	

Hamstring Tendons—Osseous Ankylosis of Knee—Ankylosis of Knee in Straight Position—Deformities of the Bones of lower Limb from Rickets—Club-foot : Talipes—Varieties—Congenital Club-foot : Talipes Equino-varus—Causation—Pathological Anatomy—Treatment—Talipes Calcaneus—Treatment—Talipes Valgus—Treatment—Acquired Club-foot : Forms—Treatment—Flat or Splay-foot : Spurious Talipes Valgus—Treatment—Hollow Claw-foot—Mode of Production—Contraction of One Toe—Hallux Flexus—Supernumerary and Webbed Toes—Congenital Hypertrophy of Toes and Foot—Weak Ankles—Bow-Leg—Treatment . . . . .	541—567
---	---------

## CHAPTER LIV.—DISEASES OF THE HEAD AND NECK.

SCALP AND SKULL—Pachydermatous Tumour of Scalp—Fungus of the Dura Mater—Nature—Symptoms—Treatment—Fungus of the Skull—Meningocele and Encephalocele—Diagnosis—Tapping and Draining the Ventricles of the Brain—Operations on the Brain—Craniectomy . . . . .	568—575
EAR—Method of Examination—AFFECTIONS OF EXTERNAL EAR AND MEATUS—Malformations—Hypertrophy—Gouty Concretions—Fibrous Tumour—Bloody Tumours or Hæmatomata—Eczema—Concretions in the Meatus—Thickening of the Cuticle—Boils—Otitis Externa—Exostoses—Periosteal Thickenings.—DISEASES OF THE MIDDLE EAR—Simple Acute, Chronic Non-Purulent, Acute Purulent, and Chronic Purulent Catarrh—Treatment—Complications of Chronic Suppuration—Mastoid Abscess—Treatment—Extradural Abscess—Septic Phlebitis of the Lateral Sinus—Symptoms—Treatment—Septic Meningitis—Abscess of the Brain—Diagnosis—Treatment—Pyæmia—Polypus—Nervous Deafness . . . . .	575—586
NOSE—EXTERNAL AFFECTIONS—Acne Rosacea—Lipoma Nasi—Lupus, Squamous Carcinoma, &c.—Ulcers and Fissures.—AFFECTIONS OF THE NASAL CAVITY—Examination of Cavity—Deviation of Septum—Chronic Catarrh—Watery Discharge—Ozæna—Chronic Thickening of Schneiderian Membrane—Nasal Reflex Neuroses—Abscess—Treatment—Necrosis—Treatment—Calculi—Epistaxis—Treatment . . . . .	586—593
TUMOURS OF THE NASAL FOSSÆ—Polypus—Varieties—Mucous Nasal Polypus—Symptoms—Diagnosis—Treatment—Naso-pharyngeal Fibroma—Prognosis—Treatment—Malignant Nasal Tumours—Treatment—Naso-orbital Tumours—Diagnosis—Treatment—Columnar Papilloma—Diseases of Frontal Sinuses . . . . .	593—601
CHEEKS—Salivary Fistula—Treatment . . . . .	601—602
LIPS—Congenital Malformation—Hypertrophy—Ulceration—Cysts and Nævi—Warty Growths—Squamous Carcinoma—Removal—Operation . . . . .	602—605
PAROTID GLAND—Parotitis or Mumps—Parotitis after Injury or Disease of Abdomen or Pelvis—Tumours—Diagnosis—Treatment—Excision of the Parotid Gland . . . . .	605—609
NECK—Congenital Fistulæ—Cystic Tumours—Solid Tumours—Hæmatoma of the Sternomastoid . . . . .	609—613
THYROID GLAND—Causes of Bronchocele—Symptoms and Varieties—Simple Hypertrophy—Fibrous Bronchocele—Cystic Bronchocele—Pulsating Bronchocele—Treatment—Injection of Tincture of Iodine—Of Perchloride of Iron—Ligature of Thyroid Arteries—Excision—Scooping out portion of Thyroid Body—Treatment of Cystic Bronchocele—Adenomata and Cysto-adenomata—Acute Bronchocele—Exophthalmic Goitre—Acute Inflammation—Tubercle—Malignant Tumours . . . . .	613—621

## CHAPTER LV.—DISEASES OF THE JAWS AND THEIR APPENDAGES.

DISEASES OF THE GUMS AND ALVEOLAR PROCESSES—Abscess—Spongy Gums—Hypertrophy—Epulis—Fibrous Epulis—Treatment—Myeloid Sarcoma of the Alveolar Border—Epithelioma—Necrosis of Jaw—Lucifer-Match Disease—Treatment—Reproduction of Jaw after removal . . . . .	622—627
DISEASES OF THE ANTRUM AND UPPER JAW—Suppuration in the Antrum—Treatment—Cystic Disease of Antrum—Treatment—Polypus of Antrum—Dental and Dentigerous Cysts—Solid Tumours—Varieties—Situation and Symptoms—Diagnosis—Treatment—Operations on the Upper Jaw—Scoping—Partial Excision of Upper Jaw—Complete Excision—Results—Tumours behind the Superior Maxilla—Langenbeck's Osteoplastic Section . . . . .	627—642
DISEASES OF THE LOWER JAW—Abscess—Acute Suppurative Periostitis—Tumours—Varieties—Cysts—Odontoma—Sarcomata—Diagnosis—Treatment—Excision of the Lower Jaw . . . . .	642—649
DISEASES OF THE TEMPORO-MAXILLARY ARTICULATION—Acute Arthritis—Ankylosis—Enlargement of Condyle of the Jaw—Closure of the Jaw: Spasmodic—Permanent . . . . .	649—651

## CHAPTER LVI.—PLASTIC SURGERY OF THE FACE AND MOUTH.

PLASTIC OR REPARATIVE SURGERY—Definition—Methods of Operating—Conditions of Success—Faulty Cicatrices—Burow's Operation—Blepharoplasty . . . . .	652—656
PLASTIC SURGERY OF THE NOSE—Restoration of Columna—Of Ala—Of Entire Nose—Tagliacotian Operation—Indian Operation—Formation and Attachment of Flap—Separation of Root of Flap—Formation of Columna Nasi—Langenbeck's and Ollier's Modifications—Fistulous Openings through Nasal Bones—Operation for Depressed Nose . . . . .	656—662
PLASTIC SURGERY OF THE LIPS—Hare-lip—Single and Double—Median Fissure—Age for Operation—Objects of Operation—Operation for Single Hare-lip—For Double Hare-lip—Congenital Transverse Fissures of Cheeks—Cheiloplasty—Buchanan's Operation for Restoring Lower Lip . . . . .	662—671
PLASTIC SURGERY OF THE PALATE—Age for Operation—Operations for Cleft Palate—Operation on Soft Palate—Sédillot's Operation—Operation on Hard Palate—After-Treatment—Perforation of the Hard Palate . . . . .	671—677

## CHAPTER LVII.—DISEASES OF THE MOUTH AND THROAT.

TONGUE—Tongue-tie—Hypertrophy and Prolapse—Glossitis—Abscess—Chronic Superficial Glossitis—Psoriasis, Leucoplakia—Prognosis—Treatment—Aphthæ—Simple Ulceration—Tuberculous Ulcer—Syphilitic Gummata—Tumours—Nævus and Aneurism by Anastomosis—Cystic and Fibrous and Fatty Tumours—Carcinoma of Tongue—Nature—Diagnosis—Treatment—Division of the Lingual Nerve—Ligature of Lingual Artery—Operations on the Tongue—Excision of a small part—Excision of Whole or Large Portion—Excision by the Ecraseur—Excision with Scissors—Submental Operations—Buccal Operation—Excision after Division of Lower Jaw—Hæmorrhage during Excision—After-Treatment—Accidents after Operation—Comparison of Methods of Operating—Results—Effect of Removal of Tongue on Speech—Solid and Cystic Tumours in Floor of Mouth—Salivary Calculi . . . . .	678—702
PALATE, UVULA, AND TONSILS—Hard Palate—Soft Palate—Elongation of the	

Uvula—Tonsillitis or Quinsy—Treatment—Chronic Enlargement of the Tonsils—Treatment—Excision of Tonsils—Malignant Tumours . . . . .	702—708
PHARYNX—Catarrhal Pharyngitis—Follicular or Granular Pharyngitis—Adenoid Vegetations—Erysipelatous Pharyngitis—Phlegmonous Pharyngitis—Acute Retropharyngeal Abscess—Treatment—Syphilitic Affections—Tumours . . . . .	708—712
ŒSOPHAGUS—Congenital Malformations—Inflammatory Affections—Varices—Ulceration—Diverticula—Simple Tumours—Sarcoma—Carcinoma—Stricture and Dysphagia—Conditions producing Dysphagia without Stricture—Diagnosis of Stricture—Hysterical or Spasmodic—Organic—Diagnosis of Organic Stricture—Treatment—Gastrostomy—Œsophagostomy—Œsophagectomy . . . . .	712—723
LARYNX—The Laryngoscope—Laryngitis—Varieties—Acute Catarrhal Laryngitis—Symptoms—Treatment—Acute Œdematous Laryngitis—Diagnosis—Treatment—Chronic Laryngitis—Varieties—Simple Chronic—Treatment—Local Medication of Larynx—Syphilitic Laryngitis—Diagnosis—Treatment—Tuberculous Laryngitis—Diagnosis—Treatment—Complications of Chronic Laryngitis—Nervous Affections of Larynx—In Children—In Adults—Paralysis of Larynx—Tumours of Larynx—Treatment—Thyrotomy—Malignant Tumours of Larynx—Complete Excision of Larynx—Operation—Partial Excision of Larynx—Results—Polypus of the Trachea . . . . .	723—738

## CHAPTER LVIII.—OPERATIONS ON THE AIR-TUBE AND ON THE CHEST.

LARYNGOTOMY AND TRACHEOTOMY—Conditions requiring Operation—Opening the Windpipe in Membranous Laryngitis—In other Forms of Laryngeal Obstruction—Necessity for Promptitude—Operations—Conditions requiring Operation—Laryngotomy—Tracheotomy—Difficulties and Accidents—Exposing the Trachea—Hæmorrhage—Opening the Trachea—Introduction of Tube—Trachea-Tubes—Tracheotomy in Children—Comparison of Laryngotomy and Tracheotomy—After-treatment of Laryngotomy and Tracheotomy—Difficulty in Establishing Natural Respiration after Tracheotomy—Intubation of the Larynx . . . . .	739—755
SURGICAL OPERATIONS ON THE CHEST—Tapping the Pleural Cavity—Surgical Treatment of Empyema—Best Point for Opening—Method of Operating—The Tube—Dressing and After-Treatment—Removal of Tube—Results—Estlander's Operation—Pneumothorax . . . . .	755—761
TAPPING PULMONARY CAVITIES—Operation—Hydatids of the Lung—Tapping the Pericardium—Drainage of the Pericardium . . . . .	761—764

## CHAPTER LIX.—DISEASES OF THE BREAST.

DISEASES OF THE BREAST—Ages at which they occur . . . . .	765
ANOMALIES OF DEVELOPMENT—Absence of Breast—Supernumerary Breasts and Nipples . . . . .	765—766
NEURALGIA—Symptoms—Treatment . . . . .	766—767
HYPERTROPHY—True—Causation—Symptoms—Diagnosis—Prognosis—Treatment . . . . .	767—768
ABNORMALITIES OF SECRETION—Agalactia—Excessive Secretion—Galactocoele . . . . .	768—770
ACUTE INFLAMMATION OF THE BREAST—Of Nipple and Areola—Treatment—Abscess of Areola—True Eczema of Nipple—Puerperal Mastitis—Mastitis Neonatorum—Mastitis of Puberty—Non-puerperal Mastitis of Adults—Acute Submammary Abscess—Treatment . . . . .	770—774
CHRONIC INFLAMMATION OF THE BREAST—Chronic Lobular Interstitial Mastitis—Pathological Appearances—Symptoms—Diagnosis—Treatment—Calcification—	

General Diffuse Inflammation—Chronic Abscess—Encysted—Diagnosis—Treatment—Submammary—Tuberculosis of the Breast—Symptoms—Pathological Anatomy—Treatment—Syphilitic Disease of Breast . . . . .	774—778
<b>TUMOURS OF THE BREAST.</b> . . . .	779
<b>CYSTS OF THE BREAST</b> —Arising in the Gland Tissue: True Glandular Cysts—Duct Cysts—Multiple Cysts—Arising Independently of the Glandular Tissue: Serous Cysts—Hydatid Cysts—Diagnosis of Cysts of the Breast—Treatment . . . . .	779—784
<b>SIMPLE TUMOURS</b> —Lipoma—Fibroma—Chondroma and Osteoma— <b>ADENOMATA</b> or <b>SIMPLE GLANDULAR TUMOURS</b> —Structure—True Adenoma—Hard Fibro-adenoma—Soft Fibro-adenoma—Cysto-adenoma—Diagnosis—Treatment . . . . .	784—791
<b>MALIGNANT TUMOURS</b> —Sarcoma—Prognosis in Sarcoma of Breast—Diagnosis of Sarcoma of Mamma—Treatment of Sarcoma of Breast— <b>CANCER OF THE BREAST</b> —Hard Glandular Carcinoma or Scirrhous—Forms: Nodular or Circumscribed—Infiltrating or Diffuse—Atrophying, Withering, or Cicatricial—Cysts—Symptoms of Cancer—Retraction of Nipple—Implication of Skin—Pain—Enlargement of Axillary Glands—Ulceration of Skin—Cancerous Cachexia—Duration of Life—Pathological Structure—Soft Glandular Carcinoma or Encephaloid—Colloid Carcinoma—Columnar Carcinoma—Causes of Cancer of Breast—Sex—Age—Social Condition—Injuries—Disease of Nipple—Diagnosis—Treatment— <b>OPERATION FOR CARCINOMA OF BREAST</b> —Selection of Cases: Favourable, Unfit, and Doubtful—Objects of Operation—Extent of Operation—Excision of Breast—Results—Recurrence of Disease after Operation—Axillomammary Carcinoma . . . . .	791—812
<b>DISEASES OF THE MALE BREAST</b> —Scirrhus Carcinoma . . . . .	813
<b>AXILLARY TUMOURS</b> —Tuberculous Disease of Axillary Glands—Simple Tumours—Lymphadenoma—Fibromata—Sarcomata . . . . .	813—815

## CHAPTER LX.—DISEASES OF THE ABDOMEN.

<b>INTRODUCTORY REMARKS</b> —Operative Treatment of Diseases of the Abdominal and Pelvic Viscera—Septic Peritonitis and Septicæmia—Bacterium coli commune—Shock—Hæmorrhage . . . . .	816—820
<b>HERNIA</b> defined—Structure—Sac—Neck—Body—Contents—Enterocœle—Epiploceœle—Entero-Epiploceœle—Adhesions—Fluid—Hydrocœle of Hernial Sac—Loose Foreign Bodies in Sac—Signs of Hernia—Intestinal—Omental—Cæcal—Hernia of Bladder or Cystocœle—Causes—Predisposing Causes—Sex—Age—Occupation—Other Causes—Conditions presented by Hernia . . . . .	821—826
<b>REDUCIBLE HERNIA</b> —Definition—Application of Truss—Radical Cure of Hernia—Operations . . . . .	826—829
<b>IRREDUCIBLE HERNIA</b> —Causes of Irreducibility—Symptoms—Treatment—Inflamed Irreducible Hernia—Treatment—Incarcerated or Obstructed Hernia—Treatment . . . . .	829—831
<b>STRANGULATED HERNIA</b> —Definition—Mechanism of Strangulation—Seat of Stricture—Local Effects of Strangulation—Inflammation of Gut after relief of Strangulation—Symptoms—Local Signs—Constitutional Symptoms—Modifications of Symptoms—Partial Enterocœle—Strangulated Omental Hernia—Diagnosis—Treatment—Taxis—Auxiliary Measures—Persistence of Symptoms after Reduction—Diagnosis—Treatment . . . . .	831—845
<b>OPERATION FOR STRANGULATED HERNIA. HERNIOTOMY</b> —Operation—Exposure of the Sac—Opening the Sac—Division of the Stricture—Reduction—Treatment of the Sac—Treatment of the Wound—After-Treatment—Accidents and Modifications of the Operation—Peritonitis—Acute Enteritis—Management of Congested Intestine: of Tightly Constricted Intestine: of Gangrenous or Ulcerated Intestine: of Adhesions: of Omentum—Sacs or Apertures in Omentum—Cysts—Wounds of the Intestine—Wounds of Arteries—Sloughing of the Sac—Artificial Anus and Fæcal Fistula—Treatment—Aspiration Treatment . . . . .	845—862

CHAPTER LXI.—SPECIAL HERNIÆ.

INGUINAL HERNIA—Varieties—Oblique : Coverings—Relations—Direct : Coverings—Relations—Incomplete—Double—Signs—Diagnosis—Hernia into Tunica Vaginalis or Congenital Hernia—Signs and Diagnosis—Encysted Hernia of Tunica Vaginalis, or Infantile Hernia—Interstitial Hernia—Inguinal Hernia in Females—Treatment—Radical Cure of Inguinal Hernia—Operation—Results—Operation for Strangulated Inguinal Hernia—Seat of Stricture—Treatment of Congenital Hernia . . . . .	863—877
FEMORAL HERNIA—Course—Relations—Contents—Signs—Diagnosis—Treatment—Radical Cure—Treatment of Strangulated Femoral Hernia—Operation . . . . .	877—883
UMBILICAL HERNIA—In Children—In Adults—Treatment—Operation—Radical Cure . . . . .	884—887
VENTRAL HERNIA—Treatment—LUMBAR HERNIA . . . . .	887—888
PELVIC HERNIÆ—Obturator—Symptoms—Treatment—Perinæal—Vaginal—Pudendal—Sciatic . . . . .	888—891
DIAPHRAGMATIC HERNIA—Congenital Defect of Diaphragm—Traumatic Diaphragmatic Hernia . . . . .	891—893

CHAPTER LXII.—INTESTINAL OBSTRUCTION.

ACUTE OBSTRUCTION—Symptoms—Varieties and Causes—Internal Strangulation—Causes—Special Symptoms—Volvulus—Special Symptoms in Sigmoid Flexure—Impaction of Foreign Bodies in Small Intestine—Special Symptoms of Obstruction from a Foreign Body—Sudden Occlusion of a Stricture of Small Intestine—Narrowing of Small Intestine—Stricture of Ileo-Cæcal Valve—Acute Intussusception—Causes—Special Symptoms.—CHRONIC OBSTRUCTION—Symptoms—Causes and Varieties—Mechanism of Obstruction of Narrowed Large Intestine—Prognosis—Fæcal Accumulation—Symptoms—Results—Chronic Intussusception—Relative frequency of various Forms of Intestinal Obstruction—Diagnosis—Acute General Peritonitis—Lead Colic—Chronic Peritonitis—Previous History—Mode of Invasion—General Condition of Patient—Character of Pain—Vomiting—Duration and Degree of Constipation—Physical Examination of Belly : Inspection—Percussion—Manipulation—Examination of Rectum—Quantity of Urine.—TREATMENT OF ACUTE OBSTRUCTION—Inversion of Patient—Puncture of Intestine—Operations for Intestinal Obstruction—Laparotomy—Enterotomy—Special Treatment of different Varieties of Acute Intestinal Obstruction—Treatment of Intussusception—Injection—Results of Operation for Acute Intestinal Obstruction—TREATMENT OF CHRONIC INTESTINAL OBSTRUCTION—Colotomy—Inguinal Colotomy—Lumbar Colotomy—Comparison of Inguinal and Lumbar Operations—Intestinal Anastomosis . . . . .	894—925
--	---------

CHAPTER LXIII.—OPERATIONS ON THE PERITONEUM AND ABDOMINAL VISCERA.—TUMOURS OF THE GROIN.

TAPPING THE ABDOMEN—PARACENTESIS ABDOMINIS . . . . .	926
LAPAROTOMY FOR PERITONITIS . . . . .	926—928
INFLAMMATION ABOUT THE CÆCUM—Typhlitis—Perityphlitic Abscess—Simple Typhlitis—Perforation of the Vermiform Appendix—Diagnosis—Relapsing Typhlitis . . . . .	928—933
REMOVAL OF PORTIONS OF THE INTESTINE . . . . .	933—934

OPERATIONS ON THE STOMACH—Perforation of Gastric Ulcer—Pylorectomy—Gastro-Enterostomy—Jejunostomy—Digital Dilatation of Pylorus for Simple Stricture, or Loretz's Operation . . . . .	934—938
OPERATIONS ON THE LIVER—Abscess—Hydatids—Resection.—OPERATIONS ON THE GALL-BLADDER—Cholecystotomy—Cholecystectomy—Cholecystenterostomy . . . . .	938—943
SPLENECTOMY—Operation . . . . .	943—944
CYSTS OF THE PANCREAS—Treatment . . . . .	945—946
DISEASES OF THE UMBILICUS—Hæmorrhage—Ulceration—Polypus—Dermoid Cysts—Squamous Carcinoma—Umbilical Fistulæ . . . . .	946—947
TUMOURS OF THE GROIN—Varieties—Treatment . . . . .	947

## CHAPTER LXIV.—DISEASES OF THE RECTUM AND ANUS.

CONGENITAL MALFORMATIONS—Narrowing and Partial Closure of Anus—Complete Closure of Anus—Anus present, Rectum wanting to a variable degree—Absence of Anus; Rectum more or less deficient—Absence of Anus, opening of Rectum into Bladder, Urethra or Vagina—Dermoids . . . . .	948—951
INFLAMMATION AND ULCERATION—Gonorrhœal Proctitis—Ulceration of the Rectum—Simple Ulcer—Tuberculous Ulceration . . . . .	952
STRICTURE: SIMPLE, SYPHILITIC, AND MALIGNANT—Simple or Fibrous—Symptoms—Progress and Termination—Treatment—Syphilitic Stricture of Rectum—Treatment—Malignant Stricture—Symptoms—Treatment—Excision of Tumour—Partial Excision of Rectum, or Proctectomy—Intussusception of Rectum—Carcinoma of Anus—Sarcoma of Rectum—Papilloma—Adenoma—Fibroma—Angioma . . . . .	953—963
RECTAL FISTULÆ—Recto-vesical Fistula—Treatment—Entero-vaginal Fistula—Recto-vaginal Fistula—Treatment—Entero-vesical Fistula . . . . .	963—965
PRURITUS ANI . . . . .	966
ULCER AND FISSURE OF THE ANUS—Pathology—Symptoms—Treatment—Spasmodic Contraction of Sphincter Ani—Atony of Rectum . . . . .	966—969
ABSCESS AND FISTULA—Acute Ischio-rectal Abscess—Chronic—Treatment—Anal Abscess—Fistula in Ano—Extent—Varieties—Complete—Incomplete or Blind—Treatment—Operation for Fistula in Ano . . . . .	969—974
HÆMORRHOIDS OR PILES—Varieties—Predisposing Causes—Age—Sex—Sedentary Life—Alcoholic Excess—Exciting Causes—Structure—External Hæmorrhoids—Symptoms—Internal Piles—Longitudinal or Fleishy—Globular—Symptoms—Hæmorrhage—Complications—Terminations—Subsidence—Coagulation—Suppuration—Sphacelus—Diagnosis: of Hæmorrhoidal Tumours—of Hæmorrhoidal Flux—Treatment: Constitutional—Local—Operation—Excision—Ligature—Cautery—Excision of affected Mucous Membrane—Dangers attending Operations for Piles . . . . .	974—987
PROLAPSUS RECTI—Partial Prolapse—Causes—Diagnosis—Treatment—Palliative—Curative—Complete Prolapse or Procidentia of the Rectum—Causes—Treatment—Protrusion of an Ovarian Cyst . . . . .	987—990

## CHAPTER LXV.—SECONDARY DISEASES OF THE URINARY ORGANS ARISING FROM SURGICAL CAUSES.—PYÆMIA AND SEPTICÆMIA IN URINARY DISEASES.

INTRODUCTORY REMARKS—Morbid Conditions of the Bladder—Diseased Conditions of the Ureters and Pelvis of the Kidney—Morbid Conditions of the Kidney—Results of Pressure—Acute Diffuse Interstitial Inflammation—Acute Interstitial Nephritis with Scattered Abscesses—Effects of Former Attacks from which

the Patient has Recovered—Causes of Interstitial Inflammation—Tension— Reflex Irritation of Kidney—Septic Matter in Pelvis of Kidney—Symptoms of Kidney Disease in Surgical Affections of Genito-Urinary Organs—Diagnosis —Urethral Fever or Uræmic Fever—Prognosis—Treatment—Pyæmia and Septicæmia in Diseases of the Urinary Organs . . . . .	991—1005
---	----------

## CHAPTER LXVI.—DISEASES OF THE KIDNEY.

STONE IN THE KIDNEY—Calculus Pyelitis—Hydronephrosis—Pyonephrosis—Peri- nephritic Abscess—Symptoms—Diagnosis—Nephrolithotomy—Nephrotomy— Nephrectomy—Examination by Abdominal Section—Complete Suppression of Urine—Calculus in Ureter . . . . .	1006—1013
MOVABLE KIDNEY—Symptoms—Diagnosis—Treatment—Nephrorrhaphy . . . . .	1013—1015
TUBERCULOUS KIDNEY—Post-mortem Appearances—Symptoms—Diagnosis—Treat- ment . . . . .	1015—1016
HYDRONEPHROSIS AND PYONEPHROSIS . . . . .	1017
TUMOURS OF THE KIDNEY—Cysts—Adenomata—Papillomata—Sarcoma—Carci- noma—Diagnosis of Renal Tumours . . . . .	1018—1020
NEPHRECTOMY—Lumbar—Abdominal—Results . . . . .	1020—1024

## CHAPTER LXVII.—URINARY CALCULUS AND LITHOTOMY.

URINARY DEPOSITS AND CALCULI—Uric Acid Deposits—Uric Acid Calculi—Treat- ment of Uric Acid Deposits—Deposits of Oxalate of Lime—Calculi—Treatment— Phosphatic Deposits—Varieties of Phosphates—Calculi—Treatment—Cystine— Xanthine or Xanthic Oxide—Carbonate of Lime—Chemical Examination of Calculi . . . . .	1025—1031
STONE IN THE BLADDER—Structure of Calculi—Origin—Number—Spontaneous Fracture—Physical Characters—Size—Weight—Hardness—Shape—Position— Causes—Age—Sex—Locality—Symptoms—Pain—Increased Frequency of Mictu- rition—Stoppage in Flow of Urine—Stone in Elderly Men—Stone in Children— Encysted Calculus—Physical Diagnosis of Stone—Sounding Bladder—Errors in Sounding—Examination with the Cystoscope—Examination by Manipulation— Pathological Changes induced by Calculus . . . . .	1031—1042
LITHOTOMY—Methods—SUPRAPUBIC LITHOTOMY—Operation—Special Dangers and Difficulties—State of Kidneys—Mortality.—LATERAL LITHOTOMY—Instruments, &c.—Operation—Position of Knife—Incision of Prostate—Extraction of Stone— After-Treatment of Lithotomy—Lateral Lithotomy in Boys—Difficulties during Lateral Lithotomy—In Finding Stone—In Entering Bladder—In Seizing and Ex- tracting Stone—From Position of Stone—From Fixture of Stone—From Spasm of Bladder—From Fibroid Tumours in Prostate—From Rickets of Pelvic Bones— From Shape and Size of Stone—From Fracture of Calculus—Accidents during Lateral Lithotomy—Hæmorrhage—Wound of Bulb—Missing the Urethra— Wound of Rectum—Wound of Posterior Part of Bladder—Difficulties in Chil- dren—Sources of Danger and Causes of Death after Lateral Lithotomy—Shock of Operation—State of Kidneys—Prolonged Operation—Hæmorrhage—Cystitis —Diffuse Inflammation of Areolar Tissue of Pelvis—From Cutting beyond Pro- state—From Bruising and Over-Distension—Peritonitis—Sloughing—Pyæmia and Septicæmia—Mortality.—MEDIAN LITHOTOMY—History—Operation—Difficul- ties and Dangers of Median Lithotomy—Difficulty in Entering the Bladder— Hæmorrhage—Wound of Bulb—Wound of Rectum—Opening up the Pelvic Fascia—Difficulty in Extraction of Stone—Mortality.—BILATERAL LITHO- TOMY.—MEDIO-BILATERAL LITHOTOMY.—RECTO-VESICAL LITHOTOMY. 1042—1075	

CHAPTER LXVIII.—URINARY CALCULUS—*continued.*

LITHOTRITY—History—Instruments—Preparation of Patient—Anæsthetics—Operation—Introduction of Lithotrite—Seizure of Stone—Crushing Stone—Removing the Fragments—Time occupied by Operation—After-Treatment—Complications—Size of Stone—Cystitis before Operation—Chronic Enlargement of Prostate—Stricture of Urethra—Sacculation of Bladder—Accidents during and after Operation—Hæmorrhage—Impaction of Angular Fragments in Urethra—Cystitis—Atony of Bladder—Disease of Kidneys—Constitutional Disturbance—Mortality.—LITHOTRITY IN BOYS—Special Dangers—Mortality.—PERINEAL LITHOTRITY	1076—1091
CHOICE OF OPERATION FOR STONE—In Boys under Puberty—Adult Males—Size and Character of Stone—Conditions of Urinary Organs—Diabetes—Result of Operations for Stone—Recurrence of Calculus after Operation—Treatment	1094—1100
URETHRAL CALCULUS—Impaction of Calculus in Urethra of Adult—In Urethra of Boy—Treatment	1100—1102
CALCULUS IN THE FEMALE—Statistics—Symptoms—Treatment—Dilatation of Urethra—Lithotritry—Lithotomy	1102—1103

## CHAPTER LXIX.—DISEASES OF THE BLADDER.

CONGENITAL MALFORMATION—Extroversion—Treatment—Ayres's Operation—Wood's Operation—Trendelenburg's Operation	1106—1110
USE OF THE CYSTOSCOPE	1110—1111
CYSTITIS—Acute—Causes—Symptoms—Pathological Changes—Termination—Treatment—CHRONIC CYSTITIS—Pathological Changes—Symptoms—Treatment	1111—1117
IRRITABILITY OF THE BLADDER—Causes—Diagnosis—Treatment—Irritable Bladder in Boys—In Women	1117—1121
ATONY OF THE BLADDER—Characters—Symptoms—Diagnosis—Results—Treatment	1121—1125
INCONTINENCE OF URINE—Passive—Distension of Bladder with Overflow—Active Incontinence—Treatment—Hysterical Retention and Incontinence—Painful Conditions of the Bladder	1125—1127
TUBERCLE OF THE BLADDER—Symptoms—Treatment	1127—1128
SACculi OF THE BLADDER	1128
TUMOURS OF THE BLADDER—SIMPLE—Symptoms—Diagnosis—Treatment—Operation—MALIGNANT—Symptoms—Treatment—Results	1129—1135
HÆMATURIA—Sources—Kidneys—Bladder—Prostate—Urethra—Treatment	1135—1137

## CHAPTER LXX.—DISEASES OF THE PROSTATE.

PROSTATITIS—Symptoms—Treatment—Prostatic Abscess—Symptoms—Treatment—Retention of Urine—Chronic Inflammation of the Prostate—Diagnosis—Treatment—Deep-seated and very Chronic Abscess	1138—1141
CHRONIC ENLARGEMENT OF THE PROSTATE—Characters—Simple Prostatic Tumours—Mechanical Effects on Urinary Organs—Moral Effects of Enlarged Prostate—Bar at Neck of Bladder—Symptoms—Complete Retention of Urine—Diagnosis—Treatment—Prostatic Catheter—Operative Treatment of Enlarged Prostate—Suprapubic Prostatectomy—Castration for Enlarged Prostate—Treatment of Complete Retention—Tapping Bladder above Pubes—Tapping Bladder from Perineum—Suprapubic Cystotomy—Atrophy of Prostate	1141—1153
PROSTATIC CALCULUS—Characters—Symptoms—Treatment	1153—1154
TUBERCLE OF THE PROSTATE	1154—1155
CARCINOMA OF THE PROSTATE—Symptoms—Treatment	1155

CHAPTER LXXI.—DISEASES OF THE URETHRA.

URETHRITIS—Symptoms—Treatment . . . . .	1156—1157
GONORRHOEA—Cause—Character—Symptoms—Incubative Stage—Acute or Inflammatory Stage—Chronic Stage—Gleet—Use of the Endoscope—Treatment of Gonorrhoea—Treatment of Gleet—Complications—Inflammation of Lymphatics of Penis—Chordee—Acute and Chronic Prostatitis—Inflammation of Neck of Bladder—Cystitis—Pyelitis and Nephritis—Retention of Urine—Hæmorrhage from Urethra—Urethral or Peri-urethral Abscess—Sequences of Gonorrhoea—Warts—Stricture—Induration and Thickening—Gonorrhoeal Epididymitis—Gonorrhoeal Inflammation of Vesiculæ Seminales—Conjunctivitis—Treatment—Sclerotitis—Treatment—Inflammation of Nose—Rheumatism—Pyæmia—Cutaneous Eruptions—Gonorrhoea in the Female—Symptoms—Diagnosis—Treatment . . . . .	1157—1173
STRICTURE OF THE URETHRA—Varieties.—SPASMODIC STRICTURE—Causes—Symptoms—Treatment.—CONGESTIVE STRICTURE—Causes—Symptoms—Treatment.—ORGANIC STRICTURE—Age—Seat—Pathological Appearances—Amount of Constriction—Dilatation of Urethra behind Stricture—Changes in Bladder—Dilatation of Ureters—Symptoms—Local Signs—Examination of Patient for Stricture—Treatment—Gradual Mechanical Dilatation—Introduction of Instruments—Results—Accidents attending Catheterism—Nervous Symptoms, Rigors, and Urethral Fever—Treatment—Suppression of Urine—Hæmorrhage—Inflammation—False Passages—Continuous Dilatation—Electrolysis—Forcible Expansion or Rupture—Sliding Tubes—Expansion by Screw Mechanism—By Wedge—Division of Stricture—Internal Urethrotomy—Result—External Urethrotomy—Operation for Permeable Stricture—Perinæal Section—Result—Excision—Comparison of Methods of Treatment—Stricture of Urethral Orifice—Impermeable Stricture—Operations for Impermeable Stricture—Operation from Behind—Operation from Front—General Results of Treatment of Stricture . . . . .	1173—1202
COMPLICATIONS AND RESULTS OF STRICTURE—Retention of Urine—Treatment—Employment of Aspirator—Tapping Bladder above Pubes—Opening Urethra behind Stricture—Extravasation of Urine—Local Effects—Constitutional Disturbance—Treatment—Perinæal Abscess—Forms—Characters—Treatment—Urinary Fistula—Treatment—Urethroplasty—Stricture of Female Urethra . . . . .	1202—1211
URINARY VAGINAL FISTULÆ—Varieties—Vesico-Vaginal—Urethro-Vaginal—Results—Treatment—After-treatment . . . . .	1212—1213
TUMOURS OF THE URETHRA—Polypoid Tumour—Vascular Caruncle—Treatment—Squamous Carcinoma . . . . .	1213—1215

CHAPTER LXXII.—DISEASES OF THE PENIS AND SCROTUM.

DISEASES OF THE PENIS—Complete Arrest of Development of Male Sexual Organs—Congenital Malformations—Adhesion of Penis to Scrotum—Hypospadias—Treatment—Epispadias—Phimosis—Congenital—Acquired—Treatment—Operations—Dilatation of Prepuce—Slitting-up Prepuce—Circumcision for Congenital Phimosis in Infants—In Boys or Adults—Paraphimosis—Treatment—Balano-Posthitis—Treatment—Herpes of Glans and Prepuce—Persistent Priapism—Gangrene of Penis—Hypertrophy of Prepuce—Warts—Horny Excrescences—Sebaceous Cysts—Fibrous Tumour of Penis—Sarcoma—Squamous Carcinoma of Penis—Causes—Diagnosis—Treatment—Amputation of Penis . . . . .	1216—1228
DISEASES OF THE SCROTUM—Hæmatoma—Inflammatory Œdema—Treatment—Squamous Carcinoma—Treatment . . . . .	1228—1229

CHAPTER LXXIII.—DISEASES OF THE TESTIS AND CORD.

MALPOSITION OF THE TESTIS—Retained Testis—Inflammation of Testis in the Inguinal Canal—Torsion of Spermatic Cord—Treatment of Misplaced Testis—Retroversion of Testicle . . . . .	1230—1233
NEURALGIA OF THE TESTIS—Causes—Treatment . . . . .	1233—1234
ACUTE INFLAMMATION OF THE TESTIS—Causes—Symptoms—Subacute Orchitis—Atrophy of Testis—Treatment of Acute and Subacute Orchitis—Strapping the Testicle—Abscess—Inflammation and Abscess of Cord—Chronic Orchitis . . . . .	1234—1237
HYDROCELE—Hydrocele of Testis—Symptoms—Congenital Hydrocele—Infantile Hydrocele—Treatment of Hydrocele—Palliative—Curative—Injection : of Iodine—of Pure Carbolic Acid—Incision and Drainage—Partial Excision of Tunica Vaginalis—Acupuncture—Encysted Hydrocele of Epididymis and of Body of Testis—Hydrocele of Cord : Encysted—Diffused . . . . .	1237—1246
HÆMATOCELE—Of Tunica Vaginalis—Characters—Symptoms—Diagnosis—Treatment—Hæmatocele of Spermatic Cord—Diagnosis—Treatment . . . . .	1246—1248
VARICOCELE—Varix, or Enlargement of Spermatic Veins—Symptoms—Diagnosis—Treatment : Palliative—Radical Cure . . . . .	1249—1251
SOLID ENLARGEMENTS OF TESTIS—Chronic Orchitis—Symptoms—Structure—Treatment—Tuberculous Disease of Testicle—Structure—Prognosis—Treatment—Syphilitic Disease of Testicle—Simple Inflammatory Form—Structure—Gummatous Form—Structure—Prognosis—Diagnosis of Simple, Tuberculous, and Syphilitic Enlargements . . . . .	1251—1259
TUMOURS OF THE TESTIS—Adenoma—Structure—Symptoms—Diagnosis—Treatment—Enchondroma of Testicle—Fibroma—Dermoid Cysts—MALIGNANT TUMOURS—Sarcoma—Treatment—Carcinoma of Testicle—Characters—Symptoms—Treatment—Undescended Testis . . . . .	1259—1263
SOLID TUMOURS OF SPERMATIC CORD—Fatty—Fibromata and Myxomata—Sarcomata . . . . .	1263
OPERATION OF CASTRATION . . . . .	1264—1265
GENERAL DIAGNOSIS OF SCROTAL TUMOURS—Reducible—Irreducible . . . . .	1265—1267
SPERMATORRHEA AND IMPOTENCE—Sexual Melancholia—TRUE SPERMATORRHEA—Diagnosis—Treatment—SPASMODIC SPERMATORRHEA—Treatment—IMPOTENCE—Sterility . . . . .	1267—1271

CHAPTER LXXIV.—DISEASES OF THE FEMALE GENERATIVE ORGANS.

INTRODUCTION OF INSTRUMENTS—Speculum Vaginæ—Female Catheter . . . . .	1272—1273
DISEASES OF THE EXTERNAL ORGANS AND VAGINA—Affections of Vulva and Labia Majora—Condylomata or Verrucæ—Fibro-cellular and Cystic Tumours—Squamous Carcinoma—Varix and Hæmatoma—Occlusion of Vaginal Outlet—Imperforate Hymen—Partially Perforate Hymen—Hypertrophy of Clitoris—Perineal Abscess—Rupture of Perinæum—Prolapse of Vagina—Congenital Absence of Vaginal Canal—Complete Absence of Uterus and Ovaries—Imperforate Vagina—Various Discharges . . . . .	1273—1278
TUMOURS OF THE UTERUS—Fibroid or Fibro-Myomatous Growths—Diagnosis—Operative Treatment—Subperitoneal Variety of Fibro-myoma—Oöphorectomy—Abdominal Hysterectomy—Submucous Variety of Fibro-myoma—Polypi—Malignant Diseases : Columnar Carcinoma—Treatment—Squamous Carcinoma—Sarcoma . . . . .	1278—1286
TUMOURS OF THE OVARY—Diagnosis—Treatment : By Medical Means—Tapping—Incision and Drainage—Other Means—OVARICTOMY—Preparation of Patient—Operation—After-treatment—PELVIC SUPPURATION—Parametric and Perimetric Abscesses—Ruptured Tubal Gestation—HERNA OF THE OVARY . . . . .	1286—1297

## LIST OF ILLUSTRATIONS TO VOL. II.

FIG.	PAGE	FIG.	PAGE
413 Hypertrophy of Toe-nail . . .	2	445 Sacculated Aneurism of Ascending Aorta. . . . .	105
414 Syphilitic Onychia. . . . .	2	446 Aorta laid open, showing Mouth of Sacculated Aneurism . . . .	105
415 Tuberculous Ulcer of Leg . . .	9	447 Dissecting Aneurism of Arch of Aorta. . . . .	106
416 Squamous Carcinoma of Leg . .	10	448 Large Aneurism of Ascending Aorta, projecting against Ribs . . .	108
417 Redent Ulcer of Back of Hand .	11	449 Posterior Tibial Nerve Flattened by Pressure of Aneurism . .	109
418 " " Perforating Skull . . .	11	450 Aneurism of Calf undergoing Spontaneous Cure : Section . . .	118
419 " " Section of (30 diams.) . .	12	451 Spontaneous Cure of Aortic Aneurism . . . . .	115
420 " " " (188 diams.) . . .	13	452 Aortic Aneurism opening into Oesophagus . . . . .	117
421 Neuroma, with nerve - filaments spread over it . . . . .	36	453 Stellate Rupture of Aortic Aneurism into Pericardium . . . .	117
422 Elephantiasis of Lower Limb . .	41	454 } Diagrams of Anel's, Hunter's, and	
423 " of the Scrotum . . . . .	42	455 } the Distal Operations . . . .	121
424 Tuberculous Glands of Neck . .	46	456 }	
425 Lymphadenoma at Root of Neck .	50	457 Femoral Artery tied for Aneurism ; laid open from Seat of Ligature to Sac . . . . .	122
426 Varicose Internal Saphenous Vein with skin attached. . . . .	63	458 Popliteal Aneurism compressing Vein : Gangrene of Limb . .	133
427 Syringe for Injecting Nævus . .	73	459 Sac laid open : cured by Compression . . . . .	135
428 Ligature of a Nævus : mode of using needles . . . . .	74	460 Sac of Tubular Aneurism, cured by Compression . . . . .	136
429 Diagram of Nævus tied . . . . .	74	461 Carte's Compressor for Middle of Thigh. . . . .	137
430 " Ligature of Flat and Elongated Nævus . . . . .	75	462 Carte's Compressor for Groin . . .	137
431 " Flat and Elongated Nævus tied . . . . .	75	463 Two Compressors applied . . .	137
432 Nævus of Lower Lip: Front-view .	78	464 P. H. Watson's Weight-Compressor . . . . .	138
433 " " " Side-view . . . . .	78	465 Tufnell's Compressor . . . . .	139
434 Large Nævus of Upper Lip: Front-view . . . . .	78	466 " " applied . . . . .	139
435 Ditto : Side-view . . . . .	78	467 Erosion of Intervertebral Substance by a Small Aneurism . . . .	154
436 Nævus of Tongue . . . . .	79	468 Aneurism of Thoracic Aorta, causing Erosion of Dorsal Vertebrae . .	154
437 Atheromatous Patch in Aorta . .	88	469 Aneurism of Arch of Aorta, bursting into Left Bronchus. . . . .	155
438 Atheromatous Material under Microscope. . . . .	90		
439 Atheroma of Aorta: Section . . .	91		
440 Annular Calcification of Artery . .	96		
441 Annular Calcification, becoming Tubular . . . . .	96		
442 Thrombosis of Two Large Branches of Abdominal Aorta . . . . .	99		
443 Embolism of Axillary Artery with Secondary Thrombosis . . . . .	99		
444 Large Fusiform Aneurism of Ascending Aorta bursting into Pericardium . . . . .	104		

FIG.	PAGE	FIG.	PAGE
470 Aneurism of Innominate, stretching Recurrent Laryngeal and dis- placing Trachea . . . . .	163	502 Anatomy of Posterior Tibial Artery	252
Diagrams of Treatment of Innomi- nate Aneurism by : Ligature of		503 Section of Bone in which deposition by Osteoblasts and absorption by Osteoclasts are in progress . . . . .	260
471 } Subclavian, Ligature of Carotid,		504 Diffuse Osteomyelitis of Humerus .	263
472 } Ligature of Subclavian and		505 Carious Bone from Tuberculous Osteitis of Skull . . . . .	265
473 } Carotid. . . . .	165	506 Tuberculous Cavity in Head of Tibia	266
474 Aneurism of Arch of Aorta, simu- lating Carotid Aneurism . . . . .	170	507 Chronic Rarefactive Osteitis of Can- cellous Tissue of Head of Tibia .	266
475 Incision for Ligature of Carotid. .	173	508 Abscess in Head of Tibia . . . . .	271
476 Anatomy of Right Carotid at Seat of Ligature. . . . .	173	509 Section of Tibia : Chronic Osteitis and Circumscribed Abscesses . .	271
477 Aneurism of External Carotid, cured by Ligature of Common Carotid .	178	510 Langenbeck's Periosteal Elevator .	273
478 } Relations of External Carotid		511 Gouge . . . . .	273
479 } Artery at Position of Ligature .	179	512 Acute Necrosis of Tibia with thin layer of New Bone . . . . .	280
480 Fusiform Aneurism of Basilar . .	181	513 Tuberculous Disease of Radius and of the Index Finger . . . . .	283
481 Aneurism of Left Internal Carotid bursting into Lateral Ventricle .	184	514 Marshall's Osteotrite. . . . .	285
482 Aneurism of Left Internal Carotid seen from below . . . . .	184	515 Central Necrosis : New Bone, Cloaca, and Included Sequestrum	291
483 Ligature of First Part of Subclavian	196	516 Reproduction of Lower Jaw after Phosphorus necrosis . . . . .	292
484 Ligature of Subclavian and Carotid for Subclavian Aneurism . . . . .	196	517 Acute Necrosis of Tibia : Deficient Formation of New Bone. . . . .	293
485 Ligature of Third Part of Subclavian	202	518 } Cutting Forceps for Removing Ne- 519 } crosed Bone . . . . .	295
486 } Anatomy of Third Part of Sub-		521 Gouge-forceps . . . . .	295
487 } clavian . . . . .	203	522 Straight Saw . . . . .	295
488 Anatomy of First Part of Axillary .	213	523 Sequestrum-forceps . . . . .	295
489 " Third " " " . . . . .	213	524 Longitudinal Section of Rickety Femur . . . . .	304
490 Incision for Ligature of Brachial at Middle of Arm . . . . .	216	525 Femur from case of Scurvy-Rickets.	305
491 Anatomy of Brachial at Middle of Arm . . . . .	216	526 Cells from Spindle-celled Sarcoma of Scapula . . . . .	314
492 Anatomy of Ulnar at Wrist . . . .	217	527 Ossifying Spindle-celled Sarcoma of Scapula : Section . . . . .	315
493 Incisions for Ligature of Brachial at Bend of Elbow, and Radial and Ulnar at Middle of Forearm and at Wrist . . . . .	218	528 Cells from Second Recurrence of above . . . . .	315
494 Anatomy of Radial at Middle of Forearm . . . . .	219	529 Myeloid Sarcoma of Head of Tibia .	316
495 Diagram of Incisions in Ligature of External Iliac, Abdominal Neph- rectomy, Ovariectomy, and Gas- trostomy . . . . .	224	530 Giant-cell from Myeloid Sarcoma .	317
496 Ligature of External Iliac : Aber- nethy's Operation . . . . .	225	531 Fusiform and Oat-shaped Cells from Myeloid Tumour. . . . .	317
497 Femoral Vein obliterated by In- guinal Aneurism . . . . .	229	532 Secondary Nodule of Calcified Sar- coma in Lung : Section . . . . .	317
498 False Aneurism of Perforating Artery . . . . .	237	533 Expansion of Lower End of Femur by Sarcoma . . . . .	318
499 Ligature of Superficial Femoral . .	241	534 Myeloid Tumour of Lower Jaw in- vading Bone : Section . . . . .	318
500 Anatomy of Superficial Femoral in Scarpa's Triangle . . . . .	242	535 Peripheral Spindle-celled Sarcoma of Shaft of Femur . . . . .	319
501 Anatomy of Femoral in Hunter's Canal. . . . .	246	536 Ditto, Amputation at Hip successful	319
		537 Malignant Growth of Head of Hu- merus . . . . .	320

FIG.	PAGE	FIG.	PAGE
533 Microscopic Section through Malignant Growth of Head of Humerus	320	574 Adams's Saw . . . . .	435
539 Vascular Erectile Tumour of one of the Parietal Bones . . . . .	324	575 Gowan's Osteotome applied to Femur	436
540 Interior of Knee disorganized by Pyæmic Arthritis . . . . .	337	576 Patient three years after Excision of Head of Femur and much of Hip-bone . . . . .	437
541 Caries at Head of Tibia . . . . .	338	577 Patient with Rectangular Ankylosis of Hip: Spine straight . . . . .	440
542 Bones from case of Tuberculous Disease of Knee Joint . . . . .	346	578 Same Patient: showing Curve of Spine allowing toes to touch ground . . . . .	440
543 Rheumatoid Arthritis of Hip: Patient . . . . .	357	579 Lines of Section of Femur in Sayre's Operation for Ankylosis of Hip . . . . .	441
544 Section of Hip affected by Rheumatoid Arthritis . . . . .	358	580 Application of Saw to Neck of Thigh-bone in Adams's Operation	441
545 Charcot's Disease of both Elbows . . . . .	360	581 Cross-legged Deformity (Lucas's case) . . . . .	442
546 Osseous Ankylosis of Hip . . . . .	362	582 Incision exposing Great Trochanter for Removal of Diseased Bone . . . . .	443
547 Butcher's Saw . . . . .	375	583 Thomas's Knee-splint . . . . .	445
548 Excision of Shoulder: Longitudinal Incision. . . . .	384	584 Thomas's Knee-splint applied . . . . .	445
549 Shoulder Stump, after Amputation by Spence's Method . . . . .	384	585 Excision of Knee by Elliptical Incision . . . . .	449
550 Excision of Shoulder: Elliptical Incision . . . . .	385	586 Application of Butcher's Saw to Head of Tibia . . . . .	450
551 Excision of Elbow: Sawing Lower End of Humerus. . . . .	389	587 } Portions of Femur and Tibia removed in Excision of Knee . . . . .	450
552 Excision of Elbow: T-shaped Incision . . . . .	391	588 } moved in Excision of Knee . . . . .	450
553 Excision of Elbow: Bones Exposed	391	589 Limb with Necrosis of Fibula . . . . .	455
554 Excision of Elbow: Longitudinal Incision . . . . .	391	590 Limb after Removal of Fibula. . . . .	455
555 Arm after Excision of Elbow . . . . .	394	591 Limb after Excision of Ankle-joint. . . . .	458
556 Arm after Removal of Radius . . . . .	395	592 Diagram of Synovial Membranes of Foot . . . . .	459
557 Radius Removed . . . . .	395	593 Foot with Disease of Os Calcis, Cuboid, and Calcaneo-Cuboid Joint . . . . .	461
558 Diagram of Bones of Wrist (Lister). . . . .	398	594 Excision of Os Calcis. . . . .	463
559 Diagram of Tendons about Wrist (Lister). . . . .	398	595 Disease of Os Calcis: Foot before and after Operation . . . . .	463
560 Lister's Splint for Excision of Wrist	400	596 Disease of Astragalus . . . . .	464
561 Hand after Excision of Wrist, fixed on Lister's Splint . . . . .	400	597 Excision of Astragalus: Foot before and after Operation . . . . .	465
562 Sacro-iliac Disease in its early stage: Sacrum . . . . .	404	598 Tuberculous Disease of Scaphoid . . . . .	467
563 Ditto: Ilium. . . . .	404	599 Disease of Cuneiform Bones . . . . .	467
564 Sacro-iliac Disease, more advanced. . . . .	404	600 Vertical Section of Spinal Cord through a Meningo-Myelocoele . . . . .	472
565 Bones from Acute Disease of Hip-joint in Adult. . . . .	411	601 Large Spina Bifida . . . . .	474
566 Position assumed by Limb on forcibly distending Hip with fluid . . . . .	416	602 Angular Curvature of Dorsal Spine	479
567 Tuberculous Disease of Hip-joint . . . . .	422	603 Caries of Lumbar Spine: no repair. . . . .	479
568 Apparatus for Extension by Weights in Hip Disease . . . . .	427	604 { Diagrams of Natural Curves of Spine: Change of Curve in Early	
569 Thomas's Hip-splint applied . . . . .	428	605 { Angular Curvature; Ditto, in	
570 Thomas's Hip-splint . . . . .	428	606 { Advanced Angular Curvature . . . . .	481
571 Perforation of Acetabulum in Tuberculous Disease of Hip. . . . .	432	607 Attitude of Child in Advanced Angular Curvature . . . . .	483
572 Carious Head of Femur from same case . . . . .	432	608 Caries of Seventh Cervical and First Dorsal Vertebra . . . . .	486
573 Barker's Flushing Curette . . . . .	435	609 Application of Sayre's Plaster Jacket	492

FIG.	PAGE	FIG.	PAGE
610 Sayre's Jacket applied . . . . .	492	656 Apparatus for use after Division of Tendo Achillis for Paralytic Equinus . . . . .	560
611 " " with Jury-Mast . . . . .	494	657 Little's Boot for Flat Foot—right side . . . . .	562
612 Enlarged Bursa over Olecranon . . . . .	503	658 Ditto, ditto, seen from behind . . . . .	562
613 Large solid Tumour of Bursa Patellæ . . . . .	507	659 Hollow Claw-Foot . . . . .	564
614 Hallux Valgus and Bunion . . . . .	510	660 { Congenital Hypertrophy of Toes and Foot: Plantar and Dorsal Aspects . . . . .	566
615 Apparatus for above Deformity . . . . .	510	662 Molluscum Fibrosum of Scalp . . . . .	568
616 Fibro-Sarcoma of Sartorius . . . . .	515	663 Temporal Bone showing Position of Lateral Sinus and point from which Mastoid Antrum may be reached . . . . .	581
617 { Back-view of and Section through above Tumour . . . . .	515	664 Diagram showing Positions for application of Trephine in Temporal and Cerebellar Abscess . . . . .	585
618 { . . . . .	515	665 Lipoma of Nose before Operation . . . . .	586
619 Sarcomatous Tumour in Sole . . . . .	516	666 Same Nose after Operation . . . . .	586
620 Section through above Tumour . . . . .	516	667 Nasal Speculum . . . . .	587
621 Double Lateral Curve . . . . .	518	668 " " (Frankel's) . . . . .	587
622 Quadruple Lateral Curve . . . . .	518	669 Bellocq's Sound. . . . .	593
623 Kyphosis . . . . .	518	670 Diagram of Plugging Nostril by means of Bellocq's Sound . . . . .	593
624 Lordosis . . . . .	518	671 Naso-Orbital Tumour . . . . .	599
625 Lateral Curvature and Rotation of Spine . . . . .	520	672 Extensive Warty Epithelioma of Lip . . . . .	603
626 Patient with Lateral Curvature . . . . .	521	673 Lines of Incision for removing V-shaped piece of Lip . . . . .	603
627 Support for Advanced Lateral Curvature . . . . .	523	674 Epithelioma of Lower Lip: Lines of Incision. . . . .	603
628 { Tenotomy-knives . . . . .	527	675 Lip after Removal of Epithelioma . . . . .	603
629 { . . . . .	527	676 Extensive Epithelioma of Lip: Lines of Incision . . . . .	604
630 { . . . . .	527	677 Epithelioma of Lower Lip involving Jaw (Heath) . . . . .	604
631 Contraction of Supinators and Extensors of Hand . . . . .	534	678 { Simple Tumour of Parotid: Front View: Back View . . . . .	607
632 Contraction of Flexors and Pronators of Hand . . . . .	534	679 { . . . . .	607
633 Dupuytren's Contraction: Dissection (Adams) . . . . .	537	680 Tumour of Parotid, too deeply seated for removal . . . . .	608
634 Supernumerary Thumb . . . . .	538	681 Cystic Hygroma of Neck . . . . .	610
635 Apparent Fusion of Two Hands . . . . .	538	682 Serous Cyst of the Thyroid . . . . .	615
636 Arrest of Development of Fingers: Left Hand: Right Hand . . . . .	539	683 Epulis of Lower Jaw . . . . .	623
637 { . . . . .	539	684 " Upper Jaw . . . . .	623

## DIVISION FOURTH.

### DISEASES OF TISSUES.

#### CHAPTER XXXVII.

##### SURGICAL DISEASES OF THE SKIN AND ITS APPENDAGES.

THE various affections peculiar to the skin, such as eczema, scabies, impetigo, acne, lepra, psoriasis, &c., fall within the province of the Surgeon, and are commonly treated by him in practice ; but, as the consideration of these would necessarily lead into the whole subject of Dermatology, the limits of this work would not allow me to discuss so extensive and special a branch of Surgery. I must therefore content myself with the consideration of some of those affections of the skin, which, requiring operative interference, may be more properly looked upon as within the scope of the present Treatise. These diseases may be considered under the several heads of Diseases of the Skin itself, including the various forms of non-malignant ulceration, and the malignant ulcers and tumours, and Diseases of the Appendages of the Skin, as the nails. We have already in Chapter VI. considered the ordinary non-malignant ulcers of the skin, and in Chapter XXXIV. some of the simple tumours that occur in connexion with the tissue.

##### DISEASES OF THE APPENDAGES OF THE SKIN.

**DISEASES OF THE NAILS.**—The nails may become diseased, as the result of mechanical injury, or as a part of some general cutaneous affection. A violent blow or pinch often partly loosens the nail and causes an extravasation of blood beneath it. It then becomes black and slowly separates. No treatment is required beyond protecting the part by some convenient covering.

In psoriasis the nails are not unfrequently affected ; the appearances vary much, but usually the nail becomes opaque and thickened, and as the result of its brittleness tends to split at its free end and may become completely separated from its matrix. Similarly the nails may become brittle and fissured in connexion with squamous syphilides as the result of the matrix becoming inflamed.

**Atrophy** of the Nails may occur as the result of any condition, local or

general, which interferes with the healthy nutrition of the matrix. The changes which may occur in the finger-nails from division of the median or ulnar nerve have already been considered. Neuritis may give rise to a similar condition.

In some broken states of health, the nails occasionally become blackish or dark-brown in colour, and are rugged, dry, and cracked, scaling off, as it were, without any apparent affection of the matrix. This condition, of which I have seen several instances, is best treated by a course of alteratives or tonics, the local condition yielding as the general health becomes improved. Arsenic will often be found of great service, either alone or with mercury.

**Hypertrophy.**—Occasionally from neglect the toe-nail may become enormously hypertrophied and twisted, looking more like a horn than a nail, as shown in the accompanying drawing (Fig. 413) taken from a patient in whom the nail had been allowed to grow uncut for twenty years, producing complete lameness. I removed the whole nail in one piece by avulsion, and completely restored the utility of the foot.

Fig. 413.—Hypertrophy and Deformity of Toe-nail.

**Onychia** is a disease of the nails dependent on inflammation of the matrix; it occurs under two forms, the *simple* and the *syphilitic*.

In **Simple Onychia** there are redness, heat, and swelling usually on one side of the nail, and in the angle of the tissue in which it is implanted; there is discharge of pus, and the nail gradually loosens, becomes dark-coloured, and somewhat shrivelled, and may eventually be thrown off, a new nail making its appearance below, which commonly assumes a somewhat thickened and rugged shape. This disease usually results from some slight injury, as the running of a thorn or splinter into the finger. The *treatment* consists in cutting away any part of the nail that becomes loose, so that no discharge may accumu-

Fig. 414.—Syphilitic Onychia.

late beneath it. The inflammation may be subdued by hot moist applications. In some cases a lotion composed of Liq. Plumb. subacetatis ʒss., Rectified spirit ʒj. and water @ Oj., will be found most efficacious. The application of iodoform is often useful.

**Syphilitic Onychia** is a more serious affection, and is often dependent on injuries inflicted on the finger during constitutional syphilis. In it a dusky-red or livid inflammation takes place at the sides or root of the nail; ulceration is set up, accompanied by the discharge of sanious and very fetid pus; and large loose granulations spring up at its root and sides, so that the end of the toe or finger that is affected (and this is most commonly either the great toe, the thumb, or the index finger) becomes greatly enlarged and bulbous in shape. The nail then shrivels, becomes brown or black, and peels off in strips (Fig. 414); after its separation, thick epidermic masses, forming abortive attempts at the production of a new nail, may develop at the base and sides. In the *Treatment*, both local and constitutional means are required. The first and most essential point is to *remove the nail*, either in whole or in part,

for it acts as a foreign body, and prevents the healing of the surface from which it springs; the ulcer may then be treated with iodoform or well rubbed with the nitrate of silver, and dressed with black wash. Colles recommends fumigating it with a mercurial candle, made by melting a drachm of cinnabar and two ounces of white wax together. The *constitutional treatment* is that of syphilis.

**Ingrowing of the Nail** is an extremely painful and troublesome affection, principally occurring in the great toe, and brought about by wearing pointed shoes, by which the sides of the soft part of the toe are pressed upon, and made to overlap the edge of the nail. An ulcer here forms, the liability to which is greatly increased by the nail being cut square, so that the flesh presses against a sharp and projecting corner of it; this ulcer discharges a foetid sanious pus, and large granulations are thrown up by it. The consequence is inability to walk or even stand with comfort.

*Treatment.*—In the very early stages before ulceration has taken place, further trouble may often be prevented by scraping the nail along its middle with a piece of broken glass or a knife, or filing it down till it is about as thin as a sheet of note-paper. At the same time, its free end should be cut short in the middle, and its corners allowed to grow well beyond the matrix, so that the natural edge of the nail and not a sharp angle shall be in contact with the soft parts. When the soft parts begin to overlap the nail various plans have been devised with a view of raising the edge of the nail, and pressing aside the soft structures. I have never, however, seen much permanent benefit result from any of these means; and the only method that is, I think, really serviceable to the patient, is the removal of the whole nail. As this operation is an excessively painful one, the patient should be anesthetized with nitrous oxide, or the matrix may be rendered insensitive by the ether spray. The Surgeon holds the diseased toe in his left hand, and then running one blade of a strong sharp-pointed pair of scissors under the nail up to its very root, he cuts through its whole length, and, removing the scissors, seizes first one half and then the other with avulsion forceps or strong dissecting forceps, and twists them away from their attachments. The surface left is still covered by the deeper layer of the epithelium, which becomes dry and hard in a few days. The back of the scissors usually wounds the matrix in the middle line, and here granulations may form. The new nail usually grows straight and healthy. In some rare cases, however, I have seen a faulty direction assumed by it. If this should happen the nail must again be removed, and the matrix dissected away. Avulsion of the toe-nail is usually unattended with danger. I was, however, once called upon to amputate a foot for gangrene, which had followed the operation performed on an elderly person.

#### DISEASES OF THE SKIN.

**LUPUS.**—Under the term *lupus* various affections of the skin were formerly included, which had but little in common with each other beyond running a chronic course and leading to destruction of the cutaneous tissues, with or without ulceration. It is now limited to two diseases which, although included under the common name, are in reality quite distinct. These affections are distinguished as *Lupus Erythematosus* and *Lupus Vulgaris*. When the term *lupus* is used alone it is applied only to the latter disease.

**Lupus Erythematosus.**—This disease was originally described as an affection of the sebaceous follicles. Hebra in 1845 gave it the name of *Seborrhoea Congestiva*. It is now generally known by the name of *Lupus Erythematosus*. It consists essentially in a chronic inflammation, affecting chiefly the sebaceous follicles and the tissues immediately surrounding them. There is an increased secretion of sebaceous matter from the follicle by which the acini of the gland become dilated and the duct widened. The parts immediately surrounding the follicle show the ordinary signs of chronic inflammation, the capillaries being dilated and the tissues infiltrated with small round cells. The disease terminates in destruction of the follicles, and the chronic inflammatory products partly degenerate and are absorbed, and partly become developed into cicatricial tissue.

The circumscribed variety of the disease is the most common. It usually commences as small red spots, isolated or in groups, and varying in size from a pin's head to a split pea. Each spot soon becomes covered by an adherent scale which is greasy to the touch. If the scale be removed it is found to be continuous with a plug of altered sebaceous matter filling the dilated duct of a sebaceous gland. These separate spots gradually coalesce into a sharply defined red patch, the colour of which disappears almost entirely on pressure. The redness is most marked around the orifices of the sebaceous follicles. The patches itch slightly, but are not actually painful. As the disease advances they slowly increase in size at the circumference, while the central parts become paler, slightly depressed, and cicatricial—the thin scar tissue being dry like parchment and often scaly. There is no tendency to suppuration or ulceration.

*Lupus erythematosus* is most common on the cheeks and nose: it tends to spread symmetrically and often after a period of many months the patch assumes a characteristic butterfly shape, a large patch on each cheek being connected by a narrow strip on the nose. The disease may occur also on the ears, lips, scalp, and the backs of the hands. It runs an extremely chronic course, often lasting many years, and causing great disfigurement. It has a great tendency to relapse after apparent cure. Attacks of erysipelas are not uncommon during its progress. The disease is much more common in females than in males. According to Crocker it occurs chiefly between the ages of eighteen and forty-five years, that is to say, beyond the age at which the onset of *lupus vulgaris* is common. No satisfactory cause of the disease has yet been discovered, and, although according to some observers there is not unfrequently a family history of phthisis, there is no evidence to shew that the inflammation of the skin is tuberculous. Tubercle bacilli have not been demonstrated, and inoculation has given negative results. The disease is not hereditary or contagious.

*Treatment.*—No drug has any specific influence on the disease, and the constitutional treatment therefore consists merely in attending to the general health on ordinary principles. Locally, Kaposi has found the application of *Emplastrum Hydrargyri* a most efficient mode of treatment; the plaster contains mercury  $\mathfrak{z}\text{iv}$ , turpentine  $\mathfrak{z}\text{ij}$ , yellow wax  $\mathfrak{z}\text{iiij}$ , and lead plaster  $\mathfrak{z}\text{jss}$ . The surface may be cleaned before its application by being smeared with oil and well washed with soft soap. The plaster should be spread thickly on thin linen, and changed daily. Strong caustics are not to be recommended, and the results obtained by the application of superficial escharotics have not been

encouraging. Painting with iodine has also been recommended. It excites a certain degree of inflammation after a few applications, in consequence of which the sebaceous plugs in the ducts of the follicles seem to become softened and discharged, thus causing temporary improvement. Crocker speaks highly of Hebra's treatment with spirit soap for cases in which there is no active congestion. Soft soap and alcohol in equal parts are well rubbed into the patch with a piece of lint or flannel. This removes the scales and sebaceous plugs. The process is repeated every few days, and, according to Crocker, a small patch may sometimes be completely cured in a few weeks. Linear scarification repeated at intervals of about a week has been found beneficial in some cases. In others the daily application of collodion has been of use.

**Lupus Vulgaris or Lupus: Pathological Appearances.**—This disease commences in the deep layer of the cutis vera. In its earliest stage circular accumulations of small round cells are seen displacing the bundles of fibrous tissue. The surrounding vessels are dilated, and new capillaries exist amongst the cells, and thus the nodule resembles in structure ordinary granulation tissue. These circular masses of cells gradually increase in size, and by their pressure destroy the tissue of the true skin and thus approach the surface, until at last the papillary layer is implicated and the new growth is covered merely by the epithelium. During this process neighbouring groups of cells coalesce, and processes of cell infiltration extend along the vessels and surround the hair bulbs and follicles, so that in its fully developed stage a lupoid tubercle consists of an infiltration, and more or less complete destruction, of the normal tissue of the skin from the papillæ to the subcutaneous fat. On examining a section of a fully developed patch, non-vascular nodules composed of a giant cell, surrounded by larger "epithelioid" cells, and again by ordinary lymphoid or small round cells, will always be met with. These are identical in appearance with the nodules of tubercle, a fact which led Friedländer and Köster to regard lupus as a local tuberculosis of the skin.

This view has received confirmation from the observations of Cornil, Leloir, Koch, and others, who have demonstrated the presence of the tubercle bacillus in the diseased tissues. The bacilli are very few in number and not easy to find. Koch states that he has never found more than one in a single giant cell. Leloir found that the inoculation of the lupoid tissue into rabbits gave rise to general tuberculosis in about half the animals experimented on, and subsequently Koch obtained a pure cultivation of the bacillus from lupus, which was successfully inoculated on guinea-pigs. That lupus vulgaris is a local tuberculosis affecting the skin is therefore the generally received opinion at the present time. A further proof of the tuberculous nature of lupus vulgaris is afforded by the reaction which follows the injection of tuberculin (see Vol. I., p. 1102).

After a patch of lupus has reached its full development, retrogressive changes take place. These may be of two kinds. In the first, some of the cells may become cloudy from fatty degeneration, break up, and be absorbed, while a development of cicatricial fibrous tissue takes place from the remainder. Thus, the process comes to an end without ulceration, and although the epithelial covering has been throughout intact, a scar results similar in appearance to that caused by a superficial burn. When the disease takes this course, it is described as *non-ulcerative lupus*, *lupus non exedens* or *lupus exfoliatus* (Kaposi). In the second form the fatty degeneration affects the whole of the

cellular mass, which then softens; the cuticle covering it is thrown off and the disintegrated caseous matter is discharged, leaving an ulcer which may slowly extend. The disease is then known as *ulcerative lupus*, *lupus exedens* or *lupus exulcerans*. These two forms are therefore mere modifications of one process; the fate of the new growth, whether it is absorbed without ulceration or whether it softens and is discharged, being due to local or constitutional conditions, of the nature of which we have no definite knowledge.

**Symptoms.**—Lupus commences in the form of small nodules, buried in the skin. They are separate from each other, and arranged in groups, or sometimes in irregular circles. At first they form red or reddish-brown patches, from a line to a quarter of an inch in diameter, which are not raised above the surface. The nodules continue slowly to develop, till after some weeks they become slightly elevated, and covered by a fine branny epidermic desquamation. Seen through the epidermis the nodules have a semi-translucent appearance, compared by Hutchinson to that of "apple-jelly." Several patches may coalesce, forming larger tubercles, and at the same time new patches appear, so that all stages of development may be observed at once in the same case. At this point the two forms of the disease diverge. In *Lupus non exedens*, the tubercle becomes paler in colour and gradually shrinks and disappears. The integument which has been affected by the disease may be in one of two states: it may either continue red, irritable, and branny, having the appearance of a thin cicatricial tissue, and in this way the greater part or the whole of the face may be affected; or it may leave a firm, white, smooth, and depressed cicatrix, exactly resembling that produced by a burn, along the margin of which the disease slowly spreads, in the form of an elevated ridge composed of soft bluish-white or reddish tubercles.

In *Lupus exedens*, instead of disappearing, the tubercles become pale in colour and softened; the epithelial covering separates, and the disintegrated cheesy mass mixed with some pus is discharged, and drying on the surface forms a scab. This process may be accompanied by considerable inflammation of the skin surrounding the lupoid patches, with heat, swelling, and pain. When the scab separates, an ulcer is seen beneath. It is sharply defined, with slightly raised edges, and usually a smooth red surface which bleeds readily. This sore may gradually extend both superficially and in depth, and when seated on the nose often leads to destruction of the alæ and columna. *Lupus vulgaris* seldom, however, spreads very deeply, although large areas of skin may be affected, and the most frightful deformity may result. Cessation and suppuration occasionally occur in the nearest lymphatic glands.

**Situation.**—Lupus may occur on any part of the body, but it is far more commonly met with on the face than elsewhere, the nose and cheeks being the parts usually attacked. It may commence on mucous membranes, but most commonly reaches them by extension from the skin. It is, however, occasionally met with as a primary disease in the pharynx and larynx. It then usually assumes the ulcerative form, and may lead to extensive destruction of the mucous membrane.

**Sex and Age.**—Lupus vulgaris occurs much more commonly in females than in males. It usually begins in early life,—according to Kaposi "rarely before the third year and almost never after puberty." Cases do, however, occasionally occur in which the disease begins much later than this, but they are rare.

**Complications.**—Beyond the deformity caused by the scars, the disease itself causes no serious consequences. As a rule it in no way affects the general health. Erysipelas not uncommonly attacks the diseased surface, and in some instances has been followed by marked improvement. Squamous carcinoma has been known to arise in a patch of lupus or in the resulting scar tissue.

**Causes.**—Lupus is commonly said to occur in scrofulous subjects, but the great majority of cases present no other sign of the strumous diathesis. There is no evidence that it is ever directly or indirectly related to syphilis. We know practically nothing of the local conditions which predispose to the invasion of the cutis by the bacillus tuberculosis, beyond the fact that in rare cases lupus commences in a scar, and occasionally as the result of direct inoculation. It is very rarely associated with tubercle of the lungs, and shows practically no tendency to give rise to general tuberculosis.

**Prognosis.**—Lupus is characterized by its slow course, and its tendency to relapse after apparent arrest; it is never, however, directly fatal.

**Diagnosis.**—The diagnosis is not always easy, the disease being especially apt to be confounded with some forms of impetigo, with tertiary syphilitic ulcerations, with rodent ulcer and with cancer. From *impetigo* it may be distinguished by the absence of pustules, and of the thick gummy crusts characteristic of that affection, as well as by the smaller extent of surface implicated, and by its more chronic course. From *tertiary syphilitic ulcerations*, especially from the ulcerating tubercular syphilide or softening cutaneous gummata, it is often very difficult to distinguish it. The history of the disease, the age of the patient at the time of invasion, and the more rapid progress of the syphilitic affection will usually enable the Surgeon to make a correct diagnosis. From *squamous carcinoma* it is distinguished with ease: in lupus the tubercles are numerous, and there are many centres of ulceration, the glands are seldom enlarged, and the disease commences in early life; in cancer the primary disease is single, the glands are early affected, the disease commences after middle life. In lupus the ulcer is flat, with sharply-cut edges; in cancer it is rugged and irregular, with hard, elevated and everted edges. The diagnosis from *rodent ulcer* will be given with that disease.

**Treatment.**—The *constitutional treatment* of lupus was formerly considered of great importance. Cod-liver oil, the iodides of potassium, mercury, and arsenic, either alone or combined with various other drugs, have been credited with a curative, or at least a beneficial influence on the disease. At the present time, however, when simple scrofulous sores and tertiary syphilitic ulcerations have been clearly distinguished from true lupus, the efficacy of drugs in the treatment of the disease has been found to be much less than was once supposed. Still, as lupus frequently occurs in patients who are in feeble health, anæmic or scrofulous, constitutional treatment must not be neglected; for it is evident that by improving the general health healing will be promoted. The diet should be carefully regulated and nutritious, and general hygienic conditions must be attended to. We have already considered the remarkable effects produced by the subcutaneous injection of tuberculin in cases of lupus vulgaris. As a practical therapeutic agent, the drug is likely to prove of very limited use, but it is thought that injections may be used with advantage after the diseased tissue has been destroyed as completely as possible by any of the local measures now to be described.

It is on the *local treatment* that we have chiefly to rely, and the only efficient means are those by which the morbid growth is completely destroyed. In the milder form, non-ulcerative lupus, or lupus non exedens, an attempt may however be made to arrest the disease without actual destruction of the growth. For this purpose mercurial plaster, painting with tincture of iodine, or with a strong solution of nitrate of silver, and the application of zinc or carbonate of lead ointment have sometimes been found efficacious. Lotions containing glycerine are especially useful as they prevent the surface from becoming dry and harsh. If the disease be situated on the face, care must be taken to avoid exposure to cold winds, dust, &c. Volkmann recommends punctiform scarification by means of an instrument composed of several small blades set closely together. The object of this treatment is to obliterate the vessels and thus arrest the growth and promote absorption of the morbid products. Should these methods fail, the only hope of arrest consists in destroying the diseased tissue. If it be limited in extent, the patch may be excised, but not unfrequently the cicatrix becomes prominent and irregular from a fibroid growth resembling keloid.

In lupus exedens destruction of the growth is the only treatment which holds out any prospect of success. In doing this the means adopted must be efficient. Feeble caustics only irritate the parts and aggravate the disease. The growth may be completely removed by excision, by scraping, by caustics, and by the actual cautery. Small isolated patches in the early stage of the disease may conveniently be treated by excision. This has also been practised recently in more extensive cases, the resulting raw surface being covered with skin grafts by Thiersch's method. Scraping gives, however, excellent results, and as a general plan of treatment can be strongly recommended. It is done by means of "sharp spoons" (Vol. I., Fig. 96, p. 265). The soft tissue of the growth is easily removed, and the sensation given by the denser healthy tissues beneath shows when the operation has been carried far enough. The bleeding is very free, but is easily arrested by pressure with dry cotton-wool. The small cavity may then be filled with a plug of wool soaked in a solution of perchloride of mercury (1 in 500) in order to destroy any bacilli that may have been left behind. In bad cases it is advisable to apply some caustic to the scraped surface to ensure the complete destruction of the growth. One of the best materials for this purpose is liquefied carbolic acid freely applied with a small piece of sponge held in forceps. Solid nitrate of silver, chloride of zinc, acid nitrate of mercury, and fuming nitric acid have all been recommended, and are all efficient. The actual cautery is easily controlled, and can often be used when other caustics are inapplicable. In most cases Paquelin's thermo-cautery is the best, but in deep cavities, as the mouth or nose, the galvanic cautery is more easily applied.

If when the case comes under observation there is considerable inflammation round the patch, it is better to subdue this by warm moist applications before adopting any of the above modes of treatment.

After the growth has been destroyed healthy granulations spring up, and the sore must be treated on ordinary principles. Vaseline and iodoform ointment often seems to promote the healthy healing of the raw surface.

However successful the treatment may appear at first, relapses are very common, but in a large number of cases as life advances the disease seems to become less acute, and finally ceases to reappear. The cicatrix that forms

after lupus is healed is thin, and readily breaks down, giving way on exposure to cold, or on the occurrence of constitutional derangement. The patient should, therefore, for some length of time after recovery, be careful not to expose himself to any such influences. The scars often lead to great deformity, drawing down the eyelids, distorting the mouth, and sometimes closing the nostrils. Various plastic operations may be required to remedy these defects.

**Scrofuloderma.**—This name is given to various forms of tuberculous ulceration attacking the skin which differ in their course and clinical features from those of ordinary lupus. The commonest form arises as a small, flat, indurated growth, commencing immediately beneath the cutis vera. The patch slowly extends till it reaches the size of a sixpence or shilling, or even larger. The skin covering it is dusky purple in colour. Finally, the mass softens, the skin gives way at one spot, and a thin curdy pus is discharged. The cavity left is covered superficially by a thin layer of undermined skin, of a dark bluish colour, which is too feeble to undertake any process of repair, but yet obtains just enough blood-supply to prevent its death. Consequently no healing will take place till it is destroyed. After this has been done the floor of the ulcer will be seen to be yellow and unhealthy, and the sore may slowly spread instead of healing.

Fig. 415.—Tuberculous Ulcer of Leg.

A precisely similar process of ulceration may have its starting point in a caseous lymphatic gland, which becomes adherent to, and finally bursts through, the overlying skin.

Sores of this kind are most common on the face and neck, but they may occur in other parts of the body (Fig. 415).

In children these tuberculous foci in the skin are very common; they are often multiple and not unfrequently associated with tuberculous disease of the bones of the fingers.

The *Treatment* consists in freely cutting away the undermined skin and removing the tuberculous tissue with a sharp spoon. The constitutional treatment is the same as for lupus.

(CARCINOMA OF THE SKIN may be either primary or secondary. **Primary Carcinoma** is met with in two forms: 1. Squamous Carcinoma, and 2. Rodent Ulcer.

**Squamous Carcinoma** or **Epithelioma.**—The structure and history of this have already been given. It is usually seated about the lips, face and scrotum, and at the orifices of the mucous canals. It may in rare cases arise from malignant transformation of an atheromatous cyst (Vol. I., p. 1008). Squamous carcinoma may originate also in an old scar or ulcer. In this way it may occur upon almost any part of the body; I have seen it on the back, the breast, the fingers, the hand, the thigh, and the sole of the foot. It then forms a foul ulcer, the floor of which is grey or sloughy, and often covered with large warty granulations and protuberant masses. The base is indurated,

the edges raised and everted, and often papillary in structure (Fig. 416). The discharge is thin and scanty, and unless the sore is treated by antiseptic applications it becomes horribly offensive.

Under the name of "*crateriform ulcer*" Hutchinson has described an acute form of squamous carcinoma, occurring on the face in positions similar to those in which rodent ulcer is common. The disease begins as a red firm tubercle, which rapidly forms an elevated mass, the summit of which breaks down into a crater-like cavity. There has been no glandular enlargement in the recorded cases. In a typical case, figured by Hutchinson in the first volume of his

Archives of Surgery, the disease affects the left upper eyelid; a similar tumour of the opposite eyelid had been removed two years previously and no local recurrence had occurred.

**Rodent Ulcer, Noli-me-tangere, or Cancroid** was formerly included under lupus exedens. It is a remarkable affection presenting the most unmistakable local malignancy, but never giving rise to secondary disease, even in the neighbouring lymphatic glands. The disease consists essentially of a malignant growth of very feeble vitality and slight activity of development. This invades the surrounding structures and destroys them, and in its turn breaks down, disintegrates, and is thrown off, thus causing a progressive destruction of tissue. The disease is especially characterized by its slow progress, by its eroding nature, and by the impossibility of healing it by all ordinary methods of treatment. It is a disease of advanced age, seldom beginning before 45 or 50. Its duration is in any given case indefinite; seldom less than five or six years, occasionally extending to twenty or thirty.

Fig. 416.—Squamous Carcinoma of Leg.

It affects individuals of either sex indiscriminately; and usually occurs in persons who are otherwise perfectly healthy. The health also is not influenced materially, if at all, by its long duration. I have seen persons, who have suffered from it for more than twenty years, in apparently robust health; but it is often eventually fatal by gradual exhaustion from the discharge or by penetrating to the membranes of the brain, unless removed by operation.

It always commences in the skin, usually on healthy integument; but occasionally it primarily affects a part which is the seat of some chronic change of structure, as a mole, a wart, or a scar. It may attack any part of the head, face, or extremities. The face is its seat of election, especially in the upper parts, such as the forehead, the side of the nose, the inner angle of the eye, or the temple. It spreads simply by continuity of tissue, never by disseminated local or secondary growths. It may invade all tissues: the skin primarily, the cartilage of the ear, the alæ and septum of the nose, the parotid gland, the conjunctiva and the eye-ball. It eats away bone, and may penetrate to the dura mater, and invade the brain. It progresses, however, by

preference superficially, not in depth; hence it seldom gives rise to hæmorrhage, even in the more advanced stages. The neighbouring lymphatic glands do not become implicated, and secondary visceral growths are never met with.

**Symptoms.**—In whatever situation it begins, its first appearance is in the shape of a tubercle or hard pimple of a brownish-red colour. This ulcerates slowly; and then the disease extends. Moore, to whom we are indebted for a most lucid account of the affection, lays especial stress on its commencement in a hard wart, and its continued extension by a hard margin. This ulcerated tubercle becomes covered by a scab; but as the process of destructive ulceration progresses, the sore becomes too large to be covered in this way, and an ulcer is left. This ulcer, which constitutes the disease, and is the "*Noli-melungere*" of the older authors, presents the following characters. It is always

Fig. 417.—Rodent Ulcer of back of hand. Amputation.

Fig. 418.—Rodent Ulcer: Perforation of Skull and exposure of Dura Mater.

single, and spreads solely by continuity of tissue. It is depressed slightly below the surface, is of a pale pink colour, with a furrowed rather than a granulating surface, resembling by its furrowed smoothness an irregular layer of pink wax, and is usually painless, except where cicatrizing. Its edges are slightly raised, the degree varying in different cases and depending on the closeness with which the destruction of the new growth follows its development. In some cases the two follow each other so closely that the ulcer appears to be a simple loss of tissue, scarcely any thickening of the edge being recognizable. Imperfect attempts at cicatrization form a peculiar feature of the ulcer. At one part of its margin it ceases to spread, and a thin blue line of epithelium begins to extend over the raw surface. This, however, never advances far; before long the spreading recommences at the edge of the apparently unaltered skin, and the thin layer of epithelium speedily disappears. This attempted cicatrization is never accompanied by any contraction of the sore. This want of contraction is a very characteristic feature of the disease. If half an eyelid is destroyed, the

remaining half retains its normal position unaltered. Consequently signs of contraction during treatment may be taken to indicate that the growth has been successfully destroyed in part at least.

The course of the disease is always progressive: more rapid in the skin, more slow in the bones and less vascular tissues, as those of a cartilaginous and fibroid character—the pinna of the ear, the sclerotic, and the septum of the nose, for instance. When it attacks bones, it penetrates deeply into their softer parts. Moore has noticed that the morbid growth in the advancing edge of the disease is always most clearly marked in cancellated bone—in the diploë, for example. The soft parts immediately contiguous to the disease are perfectly healthy and uninfiltrated; and there is never, even after many years' duration, any sign of secondary affection of the lymphatic glands. Unless

the progress of the disease be arrested by treatment, it is never interrupted, but will end in the death of the patient. This fatal termination may, however, be long delayed. The accompanying Fig. 118 is from a patient of mine who had suffered from the disease for nearly thirty years, but who was to all appearance in perfect health, although the skull was perforated, the dura mater exposed, and the pulsations of the brain distinctly visible.

**Diagnosis.**—The diagnosis has to be made from Epithelioma, Syphilis, and Lupus. The distinction from ordinary *epithelioma* is often at first difficult; but in the later stages the absence of glandular

Fig. 118.—Rodent Ulcer (30 diam.), vertical section. The general arrangement of the large cell-masses is shown; the thinned surface-epithelium can still be traced over the growth.

affection, the small amount of growth compared to the ulceration, and the prolonged course of the case, render the diagnosis easy. From *tertiary syphilis* it is clearly distinguished by the duration of the case: in syphilitic ulceration "the rate of destruction is measured by weeks; in rodent cancer by years." There is also an absence of all other signs of constitutional syphilis. From ordinary *lupus* it is distinguished by the age and healthy constitutional state of the patient, by the singleness of the ulcer, and the absence of the pink, scaly, or oedematous skin frequently found around lupus. Lupus may cicatrize and cease at any time; rodent ulcer never does. Lupus never causes death; rodent ulcer is always fatal eventually, if unrelieved by treatment.

**Pathology.**—The microscopic characters of the infiltrating growth have been examined by Moore, Hulke, Collins Warren, Colcott Fox, Thin and others. All are agreed that it is composed of groups or columns of cells of an epithelial type filling spaces in a very imperfectly developed connective

tissue stroma. The epithelial cells show generally no tendency to become squamous or to form globes. Moore, Hulke and Warren have, however, observed that under certain conditions, especially when invading the diploë of the bones of the skull, the cells may become grouped in imperfect globes, but these never have the hard corneous centre so commonly observed in true squamous carcinoma. The cell-masses are usually larger than those of squamous carcinoma (Fig. 419); the cells are mostly small and rounded or angular in shape, except the outermost cells of a cell-mass, which are often somewhat elongated (Fig. 420). The stroma is always infiltrated with small round cells, sometimes to such an extent as to resemble ordinary granulation tissue. In other cases numerous spindle-shaped or oat-shaped cells may be present. The growth is therefore properly classed with the carcinomata, being composed of cells of an epithelial type advancing in processes or columns, in spaces formed by a vascular stroma. It infiltrates and destroys the original tissues of the affected part, and by degenerating and disintegrating produces a slowly advancing loss of substance. It infects adjoining parts, so that when removed by an incision carried through apparently healthy skin, a recurrence of the disease may follow. On these grounds Moore suggested for it the name of **Rodent Cancer**. It differs from other cancerous growths in infecting merely by continuity of tissue, never by the lymphatics or blood stream, thus presenting a lower degree of malignancy than any other variety of carcinoma. Considerable difference of opinion still exists as to the point of origin of the growth. That it does not spring from the superficial epithelium is almost certain, as the cells show little or no tendency to assume the squamous form. Thin is of opinion that it arises from the spheroidal epithelium of the sweat-glands, Thiersch and Butlin from the sebaceous glands, while Fox believes it springs from the outer root-sheath of the hair-follicles.

Fig. 420.—Rodent Ulcer. A cell-mass more highly magnified (188 diams.). The individual epithelium cells are small and the peripheral cells tend to assume an elongated shape.

**Treatment.**—In the treatment, constitutional remedies are of no use, and local means alone are to be relied on. These consist: 1, in excision of the diseased part; 2, in the application of caustics; 3, in a combination of these two methods.

1. Excision of the whole ulcer with a wide margin of apparently healthy skin is by far the best treatment whenever it is practicable, especially when the sore has not attained too great a size, and when it is situated on the cheek, eyelid, or forehead. The gap left may be filled in by one of the plastic

operations which will be described when we come to speak of the Surgery of the Face.

2. If the patient objects to the use of the knife the ulcer may be best destroyed by the application of chloride of zinc paste to the whole of its surface. The best mode of applying this is to keep the chloride prepared for use, mixed with two or three parts of flour. When wanted, a sufficient quantity of this powder should be made into a stiff paste, by the addition of a little water, and then spread over the surface to be attacked by it, in a layer of about the thickness of a wafer; this should be left on for two or three hours, and then removed, the sore being covered with a wet dressing until the greyish slough that has been produced has separated, when the caustic may be re-applied as often as necessary. Besides the chloride of zinc, various other caustics may be had recourse to, each of which possesses some peculiar advantages. Nitric acid is useful, if the action required is not to be very deep; for, as it hardens and coagulates the tissues to which it is applied, it does not extend so far as the chloride. In some cases very marked benefit has been obtained by the repeated application of Salicylic Collodion ("Solvine"). If the ulcer is situated on the face the extract of Indian hemp contained in the preparation may be omitted, so as to make it colourless. Further observation is required before the value of this mode of treatment can be determined, but as a few weeks' delay is of little moment in rodent ulcer, it may always be tried in the early stages. If its application is painful the surface may previously be numbed by means of cocaine.

3. When the ulcer has attained a large size, when it is complicated in its outline, and irregular in its depth, something may yet be done to prolong life and to relieve suffering, even if no cure be ultimately to be expected. Moore proved that, unless the brain be implicated, or some large vessel involved, treatment may at least arrest the rapidity of the growth. The method which he adopted was a combined use of the knife and of chloride of zinc. By these means he removed in some cases the whole of the affected parts, leaving a huge chasm in the face, and even in one case exposing the dura mater for a considerable extent over the roof of the orbit. The operations were done on no regular plan, the incisions being directed solely by the shape of the growth, and no attempt was made to repair the deformity left. The results of these operations were, on the whole, favourable. Out of six cases three recovered, and the others were decidedly benefited, though not permanently cured. In all the cases in which the chloride of zinc came into actual contact with the dura mater, epileptiform fits occurred, but only of a temporary character.

When the disease is so extensive, or so situated, that absolutely nothing in the way of operation can be done, the Surgeon must content himself with covering the raw surface with lint soaked in glycerine and water, and protected by oiled silk. Iodoform, either dusted on or applied as an ointment composed of one drachm of the powder to an ounce of vaseline to which a small quantity of eucalyptus oil may be added, will usually be found the best application.

**Secondary Carcinoma of the Skin** may arise by direct extension from a primary growth or from a secondary tumour. The most marked examples are commonly met with in cancer of the breast. In this disease, after the primary tumour has reached the surface, numerous smooth, elevated tubercles of a dusky red or brownish colour may appear dotted in the skin

for many inches around the part first implicated. Each of these is a small scirrhus cancer identical in structure with the primary growth in the mammary gland. In other cases, fortunately rare, the skin covering the side of the chest is widely infiltrated by the malignant growth. It becomes smooth, of a brownish-red colour, and hard and rigid, like a piece of leather, from which it has received the name of the "cancerous cuirass."

**SARCOMA OF THE SKIN.**—Various forms of sarcoma are met with in the skin. *Spindle-celled* and *round-celled sarcoma* are seen here as in all other fibrous structures. Two forms, however, show a special predilection for the skin—the melanotic, and the alveolar.

**Melanotic Sarcoma** often commences in some pigmented spot, such as a mole. It forms a rounded tumour, smooth on the surface, and dark brown or black in colour. It is intensely malignant; generalisation may occur whilst the primary growth is still quite insignificant in size, and however early it may be removed, it is very apt to return both locally and in internal organs. If not removed it gradually increases and at last ulcerates, but before this takes place it often reaches a considerable size. I have met with two instances of this disease, one on the foot, the other on the hand, in women above seventy years of age. Some time after removal in both cases, brownish black patches looking like stains of Indian ink appeared on the skin in the neighbourhood of the cicatrix. These gradually developed into new tumours. In one case hundreds of these formed up the leg, varying in size from a pea to a filbert. They slowly ulcerated and life was destroyed, probably by secondary growths in the viscera, after a period of about four years from the primary manifestation of the disease.

**Alveolar Sarcoma** of the skin is rare. Its structure and general character have already been described (Vol. I., p. 1043). In some cases the growth is pigmented. It commences as a hard lump in the cutis vera, which steadily increases in size until it may form a projection raised half an inch or more above the surface, and one inch or more in diameter. At first it is covered by the cuticle which is smooth and shining, but after a time this gives way in the centre of the tumour and an ulcer is formed which may gradually extend into the substance of the tumour. The edges of the sore are slightly raised and everted, and the surface is usually yellowish or grey and yields a thin discharge. In many cases numerous fresh growths spring up around the original tumour. Thus, in a case in University College Hospital, twenty or more such tumours, varying in size from a pea to a walnut, were scattered over the leg below the knee. They grow slowly as a rule, and cause little pain. If not removed by operation, they ultimately prove fatal by gradual extension of the local growth with wide-spreading ulceration, but more commonly by the formation of secondary tumours in the viscera. It is probably this tumour that was described by Scarpa as the "scirrhus wart," as from its hardness and the local and general malignancy it usually manifests, it closely resembles scirrhus cancer.

The **Treatment of a Malignant Tumour of the Skin**, whether a carcinoma or a sarcoma, consists in its excision or in amputation of the limb affected. Its removal by excision should be effected as soon as its nature is recognized—provided it be of such a size, and so situated, that it can be freely removed with a sufficient stratum of subjacent healthy parts, and a wide border of surrounding skin. Should this be impossible, and the growth

be situated on a limb, amputation must be performed. In such circumstances the limb may be removed at no great distance above the disease; it not being necessary, as in cases of malignant tumours of the bones, to allow a joint to intervene between the seat of operation and the growth.

#### SIMPLE TUMOURS OF THE SKIN.

**Fibroma.**—Circumscribed fibrous tumours are occasionally met with in the skin, but are not common.

**True Keloid** is a fibroid growth not encapsuled, but fusing with the healthy skin at its edges. It usually occurs on the trunk, especially on the front of the chest over the sternum. It forms a flat tumour, raised about a line above the surrounding healthy skin. It is oval, rounded or irregular, and branching or radiating in form. The surface is smooth, and white or pink in tint. It is firm and elastic in consistence. It arises without known cause and most frequently upon the trunk or extremities in persons otherwise healthy. It is seldom painful, but may give rise to itching and burning sensations. It extends slowly, and although covering a wide area sometimes seems to have undergone a process of contraction like a scar, the surrounding skin being drawn in and wrinkled or puckered. After reaching a certain size it ceases to grow. It has no tendency to ulceration or to degenerative changes. The *treatment* is merely to allay uneasy sensations by sedative applications. If excised, it almost certainly returns in the scar.

Closely allied to true keloid are those fibroid growths that have a tendency to sprout up in scars, constituting **False Keloid**. It was described also by Caesar Hawkins under **Warty Tumours of Cicatrices**. This morbid condition appears to be simply an abnormal increase in the activity of the development of the cicatricial tissue, which springs up with great luxuriance. These growths are especially apt to follow the irregular cicatrization of burns, more particularly in children. I have, however, seen them in the adult, occasioned both in this way and by the irritation of a blister, and they have been known to form in the scars of leech-bites as well as in the lesions of acne and other skin eruptions. The warty cicatricial tissue develops chiefly on the chest and neck, and is commonly attended with much itching and tingling, often of a most distressing character. It is very vascular, bleeding freely when incised. The *Treatment* of these growths is not satisfactory. As a rule, they may safely be left alone. If they cause any annoyance the only treatment is to remove them with the knife if they are so situated as to make this possible, but most commonly the new scar assumes the same unhealthy condition.

**Morphœa or Circumscribed Scleroderma** is another condition in some respects resembling keloid. It is sometimes spoken of as **Addison's Keloid**. In this disease the skin is thickened and indurated in patches or bands, most commonly upon the trunk, as between the breasts. The patches are usually slightly raised above the surface, smooth, and sometimes of ivory-like whiteness. Atrophic changes may occur in the diseased skin, causing some contraction. The disease is apparently of a chronic inflammatory character; its cause is doubtful, although in some cases it has probably resulted from local irritation. Treatment can do little, if anything, for it, but spontaneous recovery may occur.

The disease known as **Molluscum Fibrosum**, in which enormous pendulous tumours composed of hypertrophied skin and subcutaneous tissue form on the buttocks, thighs, or other parts, has already been described (Vol. I., p. 1019)

**Osteomata of the Skin** have been described. They are always atheromatous cysts, the walls of which have undergone calcification, and occasionally true ossification in parts (Vol. I., p. 1007).

**Adenomata of the Skin** arising both from the sweat-glands and the sebaceous follicles have occasionally been met with, but they are very rare. When arising in connexion with the sebaceous follicles they form lobulated masses of some size, which after growing for many years may ulcerate and resemble epithelioma in appearance. On microscopic examination, they are found to be composed of a structure resembling a number of greatly enlarged follicles bound together by a vascular connective tissue.

In hypertrophy of the sweat-glands, or *adenoma sudoriparum*, the growth lies just beneath the corium, and may form a firm flat circular mass from a quarter to half an inch in thickness and sometimes reaching one inch in diameter. The skin is slightly raised over it and may be marked by the openings of the dilated glands. Microscopic examination shows the tumour to be composed of convoluted tubes, exactly resembling normal sweat-glands, but usually of greater diameter, between which is a small amount of new fibrous tissue. The fat is pushed on one side by the growth, but not invaded by it. It causes no pain, and has little tendency to ulcerate. It seems probable, however, that in some cases the epithelium may proliferate more rapidly, burst through the membrana propria of the tubules and invade the surrounding tissues. In this way, according to Klebs, a simple tubular adenoma of the sweat-glands merges into rodent cancer.

**Atheromatous and other Cysts** have already been described (Vol. I., p. 1000 *et seq.*), and **Nævi** will be described in a subsequent chapter with diseases of the blood-vessels.

**Moles** are pigmented patches of variable size in the skin, and always congenital. They are often raised above the surface of the surrounding skin and covered with hair, sometimes long and coarse. They cannot properly be classed as tumours, as they show no tendency to grow out of proportion to the rest of the body. In later life, however, a mole not unfrequently forms the starting-point of a tumour. It may gradually increase in size, becoming more and more prominent, and sometimes pedunculated. It may thus form a tumour, usually lobulated or papillary, and more or less darkly pigmented. Finally, from the friction of the clothes it may ulcerate and become very troublesome. A mole also not uncommonly forms the seat of origin of a sarcoma, or more rarely of a squamous carcinoma. A mole usually requires no treatment unless it become affected by one of the complications above mentioned, when it must at once be excised. The Surgeon is often consulted as to the possibility of removing a disfiguring mole from the face. There is no method by which this can be done without leaving a scar in its place, but if the patient prefer this to the pigmented patch, the mole may sometimes be excised with the knife. The healing may be hastened and contraction prevented by covering the raw surface with skin grafts, applied in the manner described on p. 278, Vol. I. In a case of extensive hairy mole covering the right half of the forehead, Marrant Baker obtained an excellent result by shaving off the mole to such a depth as not completely to remove the whole thickness of the corium. Contraction was in this way prevented and those parts of the scar in which the hair grew again were subsequently treated with nitric acid.

**Papillomata of the Skin, or Warts,** consist of elongated papillæ, covered by strata of thickened and hardened cuticle, usually situated about the hands and face, and chiefly affecting young people; they appear in many cases to be simple overgrowths of the cutaneous structures, coming and going without any evident cause. In other cases they are more permanent, becoming hardened and dark in colour, and continuing perhaps through life.

The *Treatment* of warts is sufficiently simple. They may readily be destroyed by the application of caustics or astringents; among the most useful of these, I have found the concentrated acetic acid and the tincture of the sesquichloride of iron. Warts usually disappear rapidly under the influence of salicylic collodion (see Vol. I., p. 1033). The remarkable fact has recently been pointed out by Colrat of Lyons that the internal administration of sulphate of magnesium often causes warts to disappear rapidly. For children 2 or 3 grains, and for adults half a drachm, should be given three times a day. Crocker, who has used this treatment with satisfactory results, recommends that the dose of the salt should be sufficient to produce two or three evacuations a day.

**Corns** consist of thickened masses of epithelium accumulated on those points on which undue pressure or friction has been exercised. They result from an overgrowth of the epithelium, consequent upon the abnormal stimulation to which the part is exposed. This is accompanied by some enlargement of the papillæ. The mass of epithelium is hard, dry, and scaly. In the central parts it may lead to some atrophy of the papillæ from pressure, and consequently the horny mass assumes a conical form, with its apex downwards, pressing on the sensitive cutis beneath, and thus causing considerable pain. When the corn is situated in places where the secretions of the skin accumulate and keep it moist, as between the toes, the excessive epithelium forms a soft pulpy mass which is easily removed, and the enlargement of the papillæ is then very evident.

The *Treatment* of ordinary corns consists in shaving or rasping them down so as to prevent the deep layers of cuticle, retained by the indurated superficial ones, from giving rise to pain by pressure on the papillæ of the cutis. The cuticle may previously be softened by dressing the toe with wet lint covered with gutta-percha tissue. The thickened epidermis may also be removed by the application of one of the numerous popular remedies known as "corn solvents." The best of them is that already mentioned (see Vol. I., p. 1033) under the name of Solvine. It must be applied daily for a few days, at the end of which time the thickened epidermis will peel off in a cake, leaving almost normal skin beneath. Relief may also be afforded by removing all pressure from the corn, by attention to the shape of the shoe, and by wearing a piece of soft leather or amadou, having a hole cut in the centre into which the corn projects. A soft corn between the toes is best treated as follows: clear away the sodden epithelium with soap and water; wash the interdigital space with tincture of belladonna and let it dry; then apply "solvine" to the corn. The toes may be separated by means of a small piece of cotton-wool moistened with tincture of belladonna, which will effectually check perspiration. Sometimes the belladonna causes eczema; its use must then at once be abandoned, and the toes washed twice a day with a concentrated solution of boric acid. Caustics should never be applied to ordinary corns; injurious consequences often being produced by these agents, especially in elderly

people, in whom fatal gangrenous inflammation may be excited by their action.

**Suppurating Corn.**—Under old and very thickened corns, a small bursa is usually found, in which pus is occasionally formed. The imprisonment of a small drop of matter under the thickened cuticle gives rise to the most intense agony, and may cause cedema and redness extending from the toe to the foot, and sometimes up the leg. The *Treatment* consists in softening the corn with a water dressing, shaving it down, and letting out the drop of pus by puncture with a lancet, when immediate relief from pain will result. If the pus is not thus let out it cannot point through the indurated cuticle, and may burrow beneath the skin for some distance before finding an exit. In such case a troublesome sinus is left which can sometimes be closed by the injection of stimulating lotions; more often, however, laying it open is the only efficient treatment.

**"Black Corn."**—This name is popularly given to a special form of warty corn, met with only on the sole of the foot, which may become the source of the greatest possible pain and inconvenience to the patient, altogether preventing his walking. It is usually of small size and circular in shape, the neighbouring cuticle being always considerably thickened. It is extremely sensitive to the touch, the patient shrinking when it is pressed upon, as if an exposed nerve had been injured. On slicing it down with a scalpel, it will be found to be composed of soft, tough, and white epidermis, arranged in tufts or small columns, in the centre of each of which a minute black dot is perceptible. Each tuft appears to be an elongated and thickened papilla, and the black speck is a small point of coagulated blood which has been effused into it. The whole group of enlarged papillæ is surrounded by a kind of wall of thickened epithelium. The *Treatment* of this variety of corn consists in destroying it with a caustic. I have found the application of either fuming nitric acid or potassa fusa, so as to destroy it thoroughly, to be the best and speediest remedy; and as this corn always occurs in young people no danger attends the use of these substances.

**PERFORATING ULCER OF THE FOOT.**—This, though not in reality a disease of the skin, is perhaps most conveniently considered here. The disease seems usually to commence in a corn situated on the sole of the foot opposite the head of one of the metatarsal bones—usually the first. This—in some cases apparently as the result of an injury—becomes inflamed and suppurates, and a sinus is left opening through the thickened cuticle. If a probe be passed into this it will be found to lead to dry and spongy bare bone on one of the phalangeal or metatarsal bones. The discharge is scanty and scarcely purulent. The ulceration may extend, forming a sore an inch or more in diameter. This is covered by feeble or unhealthy granulations. The disease is painless, and on further examination the foot will be found to be more or less widely anæsthetic. The anæsthesia may extend up the leg, but it is never associated with motor paralysis. The tendency of the disease is to extend slowly, causing further destruction of the bones and possibly completely perforating the foot. The foot is cold, and in most cases is prone to sweat profusely, the perspiration being very offensive. Both feet may be affected, and a similar disease has been seen in the hand.

Michaud, Sonnenburg, Duplay, and more lately Savory and Butlin, have pointed out that the disease is associated in many cases with thickening of the

endoneurium and atrophy of the fibres of the nerves leading to the affected spot. Savory and Butlin have also brought forward evidence to show that the sensory fibres are chiefly, if not solely, affected. Similar ulcerations are met with in some cases of locomotor ataxy, and more rarely in connexion with some peculiar cases of spina bifida (see Spina Bifida). It may therefore be concluded that the primary cause of the disease is impairment of nutrition consequent upon degenerative changes taking place either in the nerves leading to the affected parts or in that portion of the sensory columns of the cord that is in communication with the foot.

The *Treatment* is not as a rule satisfactory. In some cases the sinus can be made to heal by thorough scraping followed by efficient antiseptic treatment. Treves has pointed out that it is important to remove freely the thickened cuticle which surrounds the orifice of the sinus. This is facilitated by previously softening it by the application of poultices or fomentations. Relapse is, however, common, and pressure on the scar should be avoided by a properly arranged circular pad. If amputation becomes necessary, it should be done above the area of anæsthesia in the foot or leg. Recurrence of the ulceration in the stump has occurred in some cases.

## CHAPTER XXXVIII.

## DISEASES OF THE NERVOUS SYSTEM.

## NEURITIS.

**Inflammation of the Nerves** is of not unfrequent occurrence. The inflammation may be acute or chronic, and one or many nerves may be affected. "Multiple neuritis" is generally the result of some abnormal blood-state, such as that caused by alcoholism, rheumatism or diabetes; it also occasionally results from poisoning with certain metallic substances, as lead and arsenic, and may be associated with certain acute specific diseases, as diphtheria. The Surgeon is, however, chiefly concerned with inflammatory affections of single nerve trunks, amongst the chief causes of which may be mentioned injury, such as compression, wound and strain; and exposure to cold, giving rise to the so-called "rheumatic" form. A localized form of neuritis may also be due to gout.

**Symptoms.**—When a single nerve trunk is affected the local symptoms consist of tenderness on pressure along the course of the nerve, and severe continuous pains running down its trunk and ramifying along its branches, with occasional violent exacerbations, especially on moving or touching the part, and at night. In very rare cases the disease may assume an acute form, with some swelling along the course of the nerve, and slight pyrexia. Ordinarily the affection is chronic. It is one of the causes of neuralgia. In the later stages there may be affections of sensation and motion in the parts supplied by the affected nerve. Traumatic neuritis has already been fully described (Vol. I. p. 496).

Should the opportunity occur of examining the nerve after death in acute cases, the sheath will be found injected and swollen from inflammatory exudation. In chronic cases the perineurium and epineurium may be found indurated and increased in quantity, the nerve fibres being more or less compressed by the new fibroid tissue. The inflammation is in fact limited to the connective tissue of the nerve trunk, and the degeneration of the nerve fibres which may occur is secondary. The changes thus differ from those met with in the multiple forms of the disease, in which, as Gowers points out, the inflammation is "parenchymatous" and affects primarily the nerve fibres themselves.

**Treatment.**—In acute cases this consists in the application of leeches, according to the situation, and poppy or belladonna fomentations. In chronic cases blistering or the application of mustard plasters along the line of the nerve usually gives relief. The part in which the affected nerve is situated must if possible be kept at perfect rest. Hypodermic injections of morphia or cocaine may occasionally be required. When the affection is rheumatic, salicylate of soda is frequently of great use; in some cases the acetous extract of

colchicum is the best remedy ; when it is more chronic, and the pain is chiefly nocturnal, iodide of potassium may advantageously be given.

#### SCIATICA.

The characteristic feature of sciatica is pain of a neuralgic character in the course of the great sciatic nerve. The affection is believed in the great majority of cases to be due to chronic rheumatic inflammation of the sheath of the nerve, and some thickening of the epineurium has been recognized after death in a few instances. In other cases pain of a similar character may be the result of pressure on the nerve by tumours in the pelvis or gluteal region, or occasionally from affection of the cord or disease of the spine in the lower lumbar or sacral region. Sciatica is much more common in males than in females, and occurs most frequently between forty and fifty. It frequently arises from exposure to cold or damp.

The *Symptoms* of sciatica are pain in the buttock, the back of the thigh, and the leg below the knee. The pain may amount merely to uneasiness, or be intense and paroxysmal. It is usually aggravated by movement, often to such an extent as to render locomotion impossible. When the pain extends to the foot it is felt chiefly on the outer side, the inner being supplied by the long saphenous nerve from the lumbar plexus. By pressing with the point of the finger, tenderness will be found in the course of the nerve. This is most marked in the hollow between the trochanter and the tuberosity of the ischium, and down the back of the thigh. The external popliteal nerve is also sometimes acutely tender where it winds round the upper end of the fibula. When the patient is lying on his back, if the limb be raised with the knee extended, acute pain is felt in the buttock as soon as the sciatic nerve becomes tense. If now the knee be flexed so as to relax the nerve, flexion of the hip can be carried considerably further without pain. Numbness in some of the parts supplied by the nerve is not uncommon, especially on the outer side of the foot. Motor paralysis never results from simple sciatica, but there may be some weakness or even wasting of the limb from want of use. The affection is very chronic, often lasting many weeks or even months.

The **Diagnosis** of sciatica is made by attention to the symptoms just described. It is most frequently confounded with strumous disease or chronic rheumatic arthritis of the hip. The distinction is in most cases easily made by observing that the movements of the hip-joint are free and unaccompanied by pain, unless flexion is carried to such an extent as to render the nerve tense. In rheumatoid arthritis the grating felt in the joint on movement will usually indicate the nature of the disease ; with the "lightning pains" of locomotor ataxy it must not be confounded. In all cases of sciatica a careful examination of the buttock must be made for a tumour in that region : the lower part of the spine must be examined for signs of caries, and the finger might be passed into the rectum to feel for a pelvic tumour, as in these conditions local treatment directed to the course of the nerve could be of but little use.

**Treatment.**—The constitutional treatment already recommended for rheumatic neuritis must be adopted. The limb must be wrapped in flannel. Counter-irritation along the line of the nerve in the early stages by mustard plasters, and later on by blisters is most useful. The application of a long strip of capsicum-rubber plaster along the line of the nerve often has a good

effect. Hot baths usually give considerable relief. Stimulating applications, as the ammonia or compound camphor liniment, may be of use; and sedatives, as the opium or belladonna liniment, may ease the pain, but they do little to cure. Hypodermic injection of cocaine has proved very useful. Gowers recommends that the injections be made pretty deeply, but not into the nerve; the dose may be rapidly increased from one-twelfth to a third or half a grain. Hypodermic injections of morphia should be resorted to only when the patient is suffering from want of sleep due to the pain. They exert no curative influence.

If the constitutional treatment and external applications fail, as they very frequently do, two modes of treatment may be adopted—acupuncture and nerve-stretching.

**Acupuncture** is thus performed. The patient is laid on his face, and the tender points of the nerve found by pressure. Long fine needles are then thrust in so as if possible to puncture the nerve. When the needle touches the nerve the patient complains of a sudden pain down the thigh. The number of the needles used should not exceed six. They may be left in for a few minutes. This treatment sometimes gives permanent relief.

Our last resource is, however, **Stretching the Sciatic Nerve**. (See Vol. I., p. 498.) This operation has been more successful in sciatica than in any other painful affection for which it has been undertaken. Nocht has collected 24 cases: of these 16 were quickly, 5 slowly, relieved; in 2 the operation failed; and 1 died. Marshall finds that of 9 cases which occurred in University College Hospital, 4 were decidedly improved, 4 were relieved, and 1 failed.

The operation is thus performed. The patient is laid upon his face and a vertical incision, about three inches in length, is made a little above the middle of the back of the thigh. The deep fascia is opened and the contiguous borders of the semitendinosus and biceps are separated with the finger. The wound being now held open by copper spatulæ, the sciatic nerve comes into view and is raised out of the wound by passing the finger beneath it, the knee being flexed to relieve it from tension. It is then pulled forcibly in both directions for about five minutes. Marshall demonstrated that any force which can be applied while holding the nerve between the finger and thumb may safely be used. The experiments of Johnson, Trombetta, Ceccherelli, and others, have shown that the breaking strain of a healthy sciatic nerve is never under eighty pounds. The wound after the operation must be carefully drained and dressed by some antiseptic method, and it is better to apply an anterior splint for a week or ten days.

Some Surgeons prefer exposing the nerve at a higher point, below the lower border of the gluteus maximus. If the operation be performed at this point, the whole of the hamstring muscles together must be drawn to the inner side of the wound, and the nerve sought for external to them. If necessary, the lower fibres of the gluteus may be divided. There is no particular advantage in this mode of operating, and the resulting wound is deeper and more difficult to treat owing to its situation.

Trombetta and Billroth suggested stretching the nerve by means of forcible flexion of the hip with the knee extended and the foot flexed. That a very great strain can be put upon the nerve in this way is evident, and the method might very well be tried before proceeding to the more severe opera-

tion just described. It is best done by flexing the thigh fully on the abdomen with the knee bent, and then, while the thigh is fixed, extending the leg.

The conductivity of the sciatic nerve is not affected at all, or only to a very slight degree, by force used in the operation. It has been suggested that this acts by breaking down adhesions either amongst the fibres or between the sheath and surrounding structures. Marshall believes it acts by stretching or even rupturing the small *nervi nervorum* ramifying in the perineurium and in the epineurium, which must be more or less implicated and pressed upon by any inflammatory growth or exudation in chronic neuritis.

#### NEURALGIA.

NEURALGIA frequently occurs in surgical practice, either complicating other diseases, or as a distinct affection simulating closely various organic lesions, more especially of joints and bones.

**Symptoms.**—The pain in neuralgia is the essential symptom. It may be of two kinds: either following anatomically the course of a nerve and the distribution of its filaments; or affecting a considerable portion of the surface without reference to any special nerve. It is of all degrees of severity, sometimes moderate, sometimes unbearable, even by those who possess the greatest fortitude. When severe, it usually comes on suddenly, with a kind of shock, and continues as a sharp, darting, or tearing sensation, coursing along the trunk or ramifications of the affected nerve, the distribution of which may often be distinctly indicated by the direction the pain takes. It is often accompanied by other sensations, such as a tickling, smarting, or creeping feeling on the affected surface; it is in some instances relieved by pressure, in others increased by the slightest touch or movement of the part. Occasionally there is a spasm in the muscles supplied by the affected nerve; in other cases, there are heat and redness of the surface, with increased secretion from the neighbouring organs, as a flow of saliva or tears when the nerves of the jaw or eye are implicated. The duration of an attack may vary from a few moments to many days or months. The pain is most commonly intermittent or remittent; it is often irregularly so, but in some instances the periodicity is well marked.

**Situations.**—This disease may affect almost any part of the body; it is most commonly seated distinctly in the trunk and branches of a nerve. The divisions of the fifth pair are the most frequent seat of neuralgia; the pain may extend to all the branches of this nerve on one side of the head and face, but more commonly it is confined to one of its principal divisions, such as the infra-orbital, which is especially liable to be affected; in many instances it is seated in the temporal and dental nerves. Not unfrequently some of the terminal twigs alone of one of these nerves become the seat of intense pain; thus occasionally the affection is found limited to a patch on the cheek, brow, or temple, from which it scarcely ever shifts. The posterior branches of the dorsal spinal nerves, and the intercostals, are also very commonly affected, though not to the same extent as the fifth pair. In other cases the whole of an organ, or part, becomes the seat of neuralgia, though no one nerve may appear to be distinctly implicated: thus the testes, the breast, the uterine organs, or one of the larger joints, as the hip or knee, are occa-

sionally the seat of severe suffering of this kind. Extreme cutaneous sensibility is a marked feature in some cases: the patient wincing and suffering severely whenever the skin is pinched or touched, however lightly.

**Causes.**—The causes of this painful affection are very various: they may be constitutional or local. It seldom occurs in strong and healthy individuals, but is almost invariably associated with want of power, unless it be occasioned by some local mechanical cause. *Depressing influences* of all kinds are especially apt to produce it: thus, debilitating diseases, mental depression, and particularly exposure to malaria, are common occasioning causes; those forms of the disease that arise from malarial influences, or from exposure to simple cold and wet, usually assume a very intermitting or periodical character, and are commonly seated in the nerves of the head. The *hysterical temperament* very frequently disposes to the spinal and articular forms of neuralgia. There is no constitutional condition with which neuralgia is more frequently associated than with anæmia; hence its frequency in females. As Romberg somewhat poetically says, "Neuralgia is the prayer of the nerve for healthy blood." Various sources of *peripheral irritation*, as loaded bowels, the irritation of worms, carious teeth, uterine disease, and calculus, may be recognized as producing some of the more obscure varieties of the disease. *Exposure to cold* is a common cause.

Neuralgia may arise also from any compression exercised upon the trunk of a nerve; and in this way, indeed, some of the more intractable forms of the affection have their origin. Thus, thickening of the fibrous sheath, the pressure of a tumour of any kind, or of a piece of dead bone, may give rise to the most intense pain in the part supplied by the irritated nerve; and it is not improbable that, in many of the cases of neuralgia in the branches of the fifth nerve, pain may be owing to periosteal inflammation, or to some other disease of the osseous canals through which the divisions of the nerve pass.

**Diagnosis.**—The diagnosis of neuralgia, though usually made without any difficulty, is in some cases a little embarrassing, as the pain may occasionally simulate that of organic disease or inflammation of the part. From *organic disease* of the part that is the seat of suffering, such as the hip, the knee, the testis, or the breast, this disease may usually be distinguished by the co-existence of heightened cutaneous sensibility, the existence of the hysterical temperament, and the absence of the other signs that would accompany lesion of structure in the part affected. From *inflammation* the diagnosis is usually sufficiently easy, by attending to the intermittent character of the neuralgic pain, to its occurrence in hysterical subjects, and to the absence of the constitutional symptoms of inflammation. But occasionally when local inflammatory irritation is conjoined with the neuralgia, the diagnosis is difficult. Here the presence of cutaneous hyperæsthesia and the relief of the pain by firm pressure will indicate neuralgia; whereas, in inflammation, there is no tenderness of surface, but the suffering is aggravated by deep pressure.

**Treatment.**—The treatment of neuralgia must have reference to its cause, and will be successful or not according as this can be more or less readily removed. So long as the conditions that primarily occasion the disease persist, the pain is likely to continue: and if these conditions be irremovable, the disease may be looked upon as necessarily incurable, though the suffering may be alleviated by appropriate means. When it arises from any central

nervous affection, there may be fear of the ultimate occurrence of disease of a more serious type, such as epilepsy or insanity.

When it occurs as the consequence of anæmia, or in the hysterical temperament, the administration of the more stimulating and stronger preparations of iron, such as the sulphate or the perchloride, or the *mistura ferri composita*, either alone or in combination with quinine, with attention to the state of the bowels and of the uterine functions, and a regimen calculated to improve the general health, such as sea-bathing, the cold douche or cold sponging, will be of essential service. In some of these cases the combination of zinc, especially the valerianate, with *assafoetida*, will give relief when iron fails. When the neuralgia is distinctly periodical, quinine in full doses, or the liquor arsenicalis, will often speedily effect a cure. When it is rheumatic, occurring in debilitated subjects, and attended by distinct nocturnal exacerbations of pain, no remedy has so great an effect upon it as the iodide of potassium, especially when administered in combination with quinine. In the more protracted forms of the disease, relief may occasionally be given by attention to the state of the liver and digestive organs, by a course of some of the more purgative mineral waters, and by the occasional administration of aloetics, followed by tonic remedies. Gelsemium has been used with considerable success: the tincture may be given every six hours in 15 minim doses, or the alkaloid gelsemine may be injected subcutaneously in doses of  $\frac{1}{10}$  to  $\frac{1}{20}$  of a grain. In some cases, especially when the disease affects the branches of the fifth nerve, croton chloral hydrate in doses of  $1\frac{1}{2}$  grain to 5 grains, may give relief. Antipyrin occasionally proves useful; five to fifteen grains may be given every six hours.

Local applications of a sedative kind, such as chloroform, belladonna, aconite, opium, &c., are often useful adjuncts to constitutional treatment. Solid menthol rubbed on the part sometimes relieves the pain in neuralgia of the face. Chloral and camphor rubbed together in equal parts form a liquid which may be painted over the painful area with benefit in many cases. By far the readiest mode of affording relief locally is the hypodermic injection of from one-sixth to a quarter of a grain of morphia. More than this it is unsafe to begin with; but the quantity may be enormously increased. I have had a patient who, to relieve the pains attending cancer of the rectum and anus, required no less than six grains to be injected every twelfth hour. In some cases a single injection has cured neuralgia which has resisted all other means. Hypodermic injections of cocaine may in some cases give temporary ease. Relief may often be obtained by the use of electricity in the form of the continuous current. The positive sponge must be applied to some convenient place near the seat of pain, while the neuralgic spot is gently rubbed with the negative until the skin is reddened. In exceptional cases the relief is permanent. Granville has in some cases seen permanent relief produced by rapid light percussion by means of an instrument called a "percuteur."

In many cases all these means, however, are unfortunately unavailing, and the sufferer is doomed to an existence of almost constant pain, except at times when the disease appears to cease of itself, or has its intensity blunted by the administration of the more powerful sedatives, such as morphia hypodermically, or veratria, aconite, or atropine externally. In these distressing cases the sufferer is ready to grasp at any means of relief that is held out to him: and

**stretching of the affected nerve** is now frequently undertaken in the hope of relieving, if not completely removing, the affection. This operation has already been described (Vol. I., p. 499). It was there pointed out that the effect produced varies considerably according to the size of the nerve operated on. In small nerves, such as those of the face, the conductivity of the nerve is abolished as completely as if it had been divided, but as its continuity is not interrupted, repair always takes place, and after a time its function is restored. In the larger nerves, even when considerable force is used, the conductivity is not completely abolished, although it may be modified for a time. It is only when great force is used that the breaking up of the medullary sheath observed by Leuterman and Horsley takes place. We have seen that in sciatica, in which the disease is seated in the actual trunk of the nerve, great benefit is usually derived from nerve-stretching, and probably the same result may be hoped for when a similar condition exists in other nerves. In the majority of cases of neuralgia, however, the cause is either some peripheral irritation of the terminal branches or some central disease, and in these but little is to be expected from the operation. In the former case there might be temporary relief until repair of the nerve was accomplished : and in the latter, although experience has shown that there may be some improvement, this is only of a temporary character.

When stretching has failed, **section of the affected nerve** is not unfrequently recommended as a last chance of the removal of the disease. Simple section of the smaller nerves is now replaced by stretching, which, as has just been stated, temporarily abolishes their conductivity. Division is undertaken with the intention of permanently destroying the continuity of the nerve, and to ensure this about a third or half an inch of the trunk must be cut away. As with stretching, however, it is clear that the operation, though occasionally productive of temporary relief, cannot in most cases be expected to benefit the patient permanently ; for by it the cause of the neuralgia is not removed, and it can consequently be of service only when the pain is peripheral, occasioned by some local irritation existing between the part cut and the terminal branches of the nerve. If the neuralgia depend on any central cause, or on local irritation existing higher up than the point divided, the operation must eventually be useless. Thus, if the source of irritation exist in the terminal branches of the infra-orbital nerve, division of this trunk might be useful ; but if the pain be occasioned by any pressure to which this nerve may be subjected in its passage through its canal by a carious state of the bones, or by disease of the periosteum, it would be unavailing ; though it is remarkable that it not unfrequently happens that there is after these operations a temporary cessation of pain for a few weeks or months. In some of these cases, however, the pain shifts its seat from the branch operated upon to another division of the same trunk : thus, if the infra-orbital have been divided, the inferior dental or submental nerve becomes the seat of pain. Or this may ascend, as it were, to the point at which the nerve was divided ; thus, after amputation for neuralgia of the knee, the pain may return in the stump, and again when this is removed a second or even third time.

**Facial or Trigeminal Neuralgia** is the most common form of the disease and that for which some kind of operative interference is most often required. The pain in some cases is intense and paroxysmal, and the disease is then known as **Epileptiform neuralgia** or **Tic douloureux**. The pain

in such cases often starts from definite spots which will be found to be extremely tender on pressure. When the ophthalmic division is affected tender spots may be found at the supra-orbital notch, on the nose between the nasal bone and cartilage, and on the scalp above the parietal eminence. In neuralgia of the superior maxillary division tenderness may be found over the infra-orbital foramen, over the malar foramen in the malar bone, and rarely along the upper gum and in the palate. Tender spots along the branches of the inferior maxillary may be found at the mental foramen, along the side of the tongue, and sometimes in front of the ear and in the lower lip.

In considering the various operations which may be required for the relief of trigeminal neuralgia, it will be convenient to consider first the methods by which the different branches may be stretched or excised.

**First or Ophthalmic Division of the Fifth.**—It is evident that the frontal branch of this nerve is the only part that can be either stretched or divided. The frontal divides about the middle of the orbit into the supratrochlear and supra-orbital branches. The supra-orbital leaves the orbit usually as a single trunk, and can be isolated without difficulty. The position of the nerve is recognized by feeling for the supra-orbital notch, through which it passes. The nerve may be stretched subcutaneously by making a small puncture with a tenotome about a quarter of an inch on one side of the notch. A blunt hook is inserted through this and forcibly scraped along the bone until its point has passed the line of the nerve. The skin of the forehead must be pulled upwards so as to make it tense, and there will then be no difficulty in ascertaining by the sense of resistance whether the nerve has been hooked or not. If it be felt upon the hook, the skin of the forehead being pulled forcibly upwards, the nerve may be firmly stretched.

It is, however, better to expose the nerve by an incision through which stretching or excision may be done. The skin of the forehead must be drawn up and the eyelid down, and a curved incision about an inch in length must be made parallel to the eyebrow and a little below it, the centre of the wound being opposite the notch. The fibres of the orbicularis palpebrarum may then be separated by a blunt instrument, and the nerve exposed as it leaves the orbit lying closely upon the bone. It may then be stretched, or a piece cut out as desired. Horsley finds that the nerve can usually be traced back without difficulty to the division of the frontal, and thus the supratrochlear nerve can also be divided.

The supratrochlear is too small, and, as a rule, too much broken up into branches to be isolated and stretched. Should it be necessary to expose the nerve separately, it will be found at a point where a line drawn upwards from the angle of the mouth through the inner canthus meets the margin of the orbit.

**The Second or Superior Maxillary Branch of the Fifth.**—This nerve, after crossing the spheno-maxillary fossa, enters a canal in the floor of the orbit, and appears on the face through the infra-orbital foramen. The nerve has been divided as it leaves the foramen, in the canal, and in the spheno-maxillary fossa. The situation of the infra-orbital foramen is found by drawing a line from the supra-orbital notch to the interval between the two bicuspid teeth of the lower jaw. This line crosses the infra-orbital foramen, and if prolonged will show the position also of the mental foramen. The infra-orbital foramen is situated about half an inch below the lower margin of

the orbit. The nerve lies rather deeply, but can be stretched subcutaneously in the same way as the supra-orbital, by puncturing the skin with a tenotome and grappling for the nerve with a blunt hook, the point of which is made to scrape along the bone below the foramen. When stretching it, the upper lip and cheek must be drawn forcibly downwards. Subcutaneous section can be done in the same situation with a tenotome. To expose the nerve a curved incision, arranged so as to fall into the lines of the face, and about one inch in length, should be made with its mid-point over the foramen. After dividing the skin the levator labii superioris must be cut through, and the nerve then comes into view, and when the bleeding has been arrested, can be exposed and stretched or excised. This operation, however, can be of little use when the teeth are the seat of the neuralgic pain, as the anterior dental nerve is not affected by the section. To divide this, it is recommended by Malgaigne to make the incision parallel to the margin of the orbit and immediately below it. A few fibres of the orbicularis palpebrarum are cut through, the origin of the levator labii superioris turned down and the nerve thus exposed at the foramen. The palpebral ligament is then separated from the margin of the orbit, and pushed upwards with the fat and the eyeball so as to expose the floor of the orbit. The nerve is next cut through as it lies in the canal in the floor of the orbit, with a strong tenotome, which is made to penetrate the antrum, and the terminal branch being seized in a pair of forceps at the infra-orbital foramen, it is forcibly dragged out of the canal by which the anterior dental branches are ruptured. The free part is then cut off. This operation is apt to be followed by suppuration in the antrum and orbit. Langenbeck and Hüter have recommended that instead of opening up the orbit, the nerve should be divided subcutaneously just before it enters the canal. To do this a puncture is made in the skin immediately below the outer commissure of the lids, and a blunt tenotome is pushed backwards and downwards till its point is felt to be in the speno-maxillary fissure. The nerve is then pulled forcibly where it has been exposed at the infra-orbital foramen, while the tenotome is made to shave along the maxillary border of the fissure. As soon as the trunk is divided, it can be pulled out of the canal.

On account of the frequent failure of these simpler methods numerous operations have been devised for the free excision of the superior maxillary nerve with or without Meckel's ganglion. This may be done through the antrum, as recommended by Carnochan. A V-shaped incision is made below the orbit, one limb commencing on the lower margin near the inner canthus, the other beginning half an inch below the outer canthus, and the two joining each other at a point below the infra-orbital foramen. The flap is turned upwards and the nerve traced to the canal. From the apex of the V an incision is made vertically downwards through the cheek and upper lip into the mouth. The whole anterior wall of the antrum is then exposed by raising the flap with the periosteum from the bone. The palpebral ligament is then divided and the fat of the orbit raised. A small piece of the margin of the orbit must then be cut away, so as to expose the nerve in its canal, the antrum being opened at the same time. The anterior wall of the antrum must then be freely removed, so as to give sufficient room. The posterior wall is next perforated with a chisel or trephine and the fragments removed, so as to open up the speno-maxillary fossa. The nerve may now be followed back and divided

in such cases often starts from definite spots which will be found to be extremely tender on pressure. When the ophthalmic division is affected tender spots may be found at the supra-orbital notch, on the nose between the nasal bone and cartilage, and on the scalp above the parietal eminence. In neuralgia of the superior maxillary division tenderness may be found over the infra-orbital foramen, over the malar foramen in the malar bone, and rarely along the upper gum and in the palate. Tender spots along the branches of the inferior maxillary may be found at the mental foramen, along the side of the tongue, and sometimes in front of the ear and in the lower lip.

In considering the various operations which may be required for the relief of trigeminal neuralgia, it will be convenient to consider first the methods by which the different branches may be stretched or excised.

**First or Ophthalmic Division of the Fifth.**—It is evident that the frontal branch of this nerve is the only part that can be either stretched or divided. The frontal divides about the middle of the orbit into the supratrochlear and supra-orbital branches. The supra-orbital leaves the orbit usually as a single trunk, and can be isolated without difficulty. The position of the nerve is recognized by feeling for the supra-orbital notch, through which it passes. The nerve may be stretched subcutaneously by making a small puncture with a tenotome about a quarter of an inch on one side of the notch. A blunt hook is inserted through this and forcibly scraped along the bone until its point has passed the line of the nerve. The skin of the forehead must be pulled upwards so as to make it tense, and there will then be no difficulty in ascertaining by the sense of resistance whether the nerve has been hooked or not. If it be felt upon the hook, the skin of the forehead being pulled forcibly upwards, the nerve may be firmly stretched.

It is, however, better to expose the nerve by an incision through which stretching or excision may be done. The skin of the forehead must be drawn up and the eyelid down, and a curved incision about an inch in length must be made parallel to the eyebrow and a little below it, the centre of the wound being opposite the notch. The fibres of the orbicularis palpebrarum may then be separated by a blunt instrument, and the nerve exposed as it leaves the orbit lying closely upon the bone. It may then be stretched, or a piece cut out as desired. Horsley finds that the nerve can usually be traced back without difficulty to the division of the frontal, and thus the supratrochlear nerve can also be divided.

The supratrochlear is too small, and, as a rule, too much broken up into branches to be isolated and stretched. Should it be necessary to expose the nerve separately, it will be found at a point where a line drawn upwards from the angle of the mouth through the inner canthus meets the margin of the orbit.

**The Second or Superior Maxillary Branch of the Fifth.**—This nerve, after crossing the sphenomaxillary fossa, enters a canal in the floor of the orbit, and appears on the face through the infra-orbital foramen. The nerve has been divided as it leaves the foramen, in the canal, and in the sphenomaxillary fossa. The situation of the infra-orbital foramen is found by drawing a line from the supra-orbital notch to the interval between the two bicuspids teeth of the lower jaw. This line crosses the infra-orbital foramen, and if prolonged will show the position also of the mental foramen. The infra-orbital foramen is situated about half an inch below the lower margin of

blunt hook forced through the mucous membrane, the tongue being drawn to the opposite side while the nerve is being pulled upon. Section can be made by putting the nerve on the stretch, and passing a curved bistoury to the inner side of it opposite the last molar tooth, and then cutting towards the jaw. To remove a piece, a longitudinal incision should be made through the mucous membrane in the line of the nerve, which may then be drawn out with a blunt hook.

The *mental branch of the inferior dental* is easily reached, as it emerges from the dental canal. The foramen is situated directly below the interval between the bicuspid teeth. The nerve can be stretched subcutaneously by making a puncture in the skin opposite the first bicuspid at such a level as not to penetrate the mouth. A blunt hook is inserted through this, and forcibly scraped along the bone across the line of the nerve. The lip and chin must be pulled inwards while the nerve is stretched. The nerve may also be exposed, and a piece cut out if desired by a small incision in the same situation.

The *main trunk of the inferior dental nerve* has been divided within the mouth through a short vertical incision along the anterior border of the ramus of the jaw. The soft parts, including the periosteum, are turned from the bone and the nerve exposed as it enters the dental foramen. Various methods have also been devised for exposing the nerve in the dental canal, by turning the soft parts from the jaw and opening the canal with a trephine or chisel.

The *auriculo-temporal nerve* can be reached where it crosses the root of the zygoma after emerging from above the parotid gland. It lies immediately behind the temporal artery. In this situation it can be exposed by a small incision parallel to its course, and immediately in front of the tragus, care being taken to avoid the artery. Subcutaneous stretching had better not be attempted for fear of injuring the temporal artery.

The *buccal nerve* has been divided from the mouth by an incision through the mucous membrane opposite the middle of the anterior border of the ascending ramus.

The results of these operations have been far from satisfactory. Cases of permanent cure have been recorded, but as a rule the relief has been temporary, lasting only a few weeks or months. This is especially true of those cases in which the pain is referred to the distribution of the inferior dental nerve. The more radical measure has therefore been adopted of excising this nerve between the skull and the dental foramen, by various operations which are also available for excision of the lingual, or even of the third division itself below the foramen ovale. The different procedures were fully described by William Rose in his Lettsomian Lectures of 1892. Horsley recommends the following operation, which has also been adopted by Rose and others. The eye is closed by a horse-hair suture passed through a fold of skin in each lid to protect it from the antiseptic lotions. An incision is made from above the upper border of the root of the zygoma straight down in front of the tragus as far as the angle of the jaw, where it turns forwards just below the lower border of the jaw as far as the facial artery. The triangular flap thus marked out is turned forwards and upwards, until the anterior border of the masseter is reached. The edge of the parotid gland and the lower border of Stenson's duct are then defined. The masseteric fascia is divided transversely between Stenson's duct and the highest branch of the facial nerve; then the

near the foramen rotundum. In doing this the termination of the internal maxillary artery may be wounded. If this happens the vessel may be twisted or tied, or if this fails the bleeding may be arrested by the caутery. Various modifications of this method have been employed by Chavasse, Treves, and others.

Suppuration in the cavity of the antrum has not unfrequently followed. In a case operated on by this method in University College Hospital, after avulsion of the nerve at the infra-orbital foramen had failed, a mucous polypus of considerable size was found in the antrum. The operation was followed by perfect relief of the neuralgia, but the cavity continued to discharge pus for several months, and as the normal aperture did not allow sufficient drainage, the lower angle of the wound had to be kept open by a tube. Possibly this might have been avoided by making an opening from the lowest part of the antrum into the nose at the time of the operation through which the cavity might have been syringed out with an antiseptic fluid.

Wagner, Horsley and others recommend that the nerve be traced backwards in the orbit. Horsley operates as follows :—An incision, dividing the periosteum, is made along the inferior orbital margin and a short one at right angles to it over the infra-orbital foramen. The periosteum is turned down from the jaw until the nerve is exposed and can be divided at its exit from the foramen. The periosteum is next separated from the floor of the orbit, and the infra-orbital canal opened up with sharp-pointed bone forceps. In this way the nerve can be followed back and divided where it leaves the foramen rotundum. Horsley recommends that, before beginning the operation, the eyelids should be stitched together with horse-hair to lessen the risk of conjunctivitis.

Braun, Lucke, Lössen, and others have operated in the pterygo-maxillary region. In order to expose the nerve in this way, an incision is commenced just behind the middle of the outer margin of the orbit, and carried downwards to a point opposite the last upper molar. From the upper end of this another is carried backwards to the root of the zygoma. The malar bone and zygoma are cut through, and the arch turned down with the masseter attached. The fat beneath is then pushed back, and if necessary some of the fibres of the temporal muscle which are inserted into the posterior part of the coronoid process of the jaw are divided. The posterior part of the superior maxilla is then recognized and followed upwards and backwards to the sphenomaxillary fossa. The nerve is next raised with a blunt hook and divided, as large a piece as possible being removed. As the internal maxillary artery and a plexus of veins which lie in the fat may cause troublesome hæmorrhage, the dissection should be carried out with a blunt instrument. After the operation the malar bone is replaced and secured by sutures. In some of the cases in which the operation has been performed considerable stiffness of the jaw has been left.

**Third or Inferior Maxillary Division of the Fifth.**—The chief branches of this nerve, the lingual, inferior dental, auriculo-temporal and buccal, have been submitted to operative treatment in neuralgia.

The *lingual* is easily reached from within the mouth. It runs obliquely forwards to the side of the tongue from a point immediately internal to the last molar tooth. It is covered only by the mucous membrane, and forms a distinct ridge if the tongue be pulled forcibly outwards and to the opposite side. In this situation, the nerve can readily be seized and stretched by means of a

blunt hook forced through the mucous membrane, the tongue being drawn to the opposite side while the nerve is being pulled upon. Section can be made by putting the nerve on the stretch, and passing a curved bistoury to the inner side of it opposite the last molar tooth, and then cutting towards the jaw. To remove a piece, a longitudinal incision should be made through the mucous membrane in the line of the nerve, which may then be drawn out with a blunt hook.

The *mental branch of the inferior dental* is easily reached, as it emerges from the dental canal. The foramen is situated directly below the interval between the bicuspid teeth. The nerve can be stretched subcutaneously by making a puncture in the skin opposite the first bicuspid at such a level as not to penetrate the mouth. A blunt hook is inserted through this, and forcibly scraped along the bone across the line of the nerve. The lip and chin must be pulled inwards while the nerve is stretched. The nerve may also be exposed, and a piece cut out if desired by a small incision in the same situation.

The *main trunk of the inferior dental nerve* has been divided within the mouth through a short vertical incision along the anterior border of the ramus of the jaw. The soft parts, including the periosteum, are turned from the bone and the nerve exposed as it enters the dental foramen. Various methods have also been devised for exposing the nerve in the dental canal, by turning the soft parts from the jaw and opening the canal with a trephine or chisel.

The *auriculo-temporal nerve* can be reached where it crosses the root of the zygoma after emerging from above the parotid gland. It lies immediately behind the temporal artery. In this situation it can be exposed by a small incision parallel to its course, and immediately in front of the tragus, care being taken to avoid the artery. Subcutaneous stretching had better not be attempted for fear of injuring the temporal artery.

The *buccal nerve* has been divided from the mouth by an incision through the mucous membrane opposite the middle of the anterior border of the ascending ramus.

The results of these operations have been far from satisfactory. Cases of permanent cure have been recorded, but as a rule the relief has been temporary, lasting only a few weeks or months. This is especially true of those cases in which the pain is referred to the distribution of the inferior dental nerve. The more radical measure has therefore been adopted of excising this nerve between the skull and the dental foramen, by various operations which are also available for excision of the lingual, or even of the third division itself below the foramen ovale. The different procedures were fully described by William Rose in his Lettsomian Lectures of 1892. Horsley recommends the following operation, which has also been adopted by Rose and others. The eye is closed by a horse-hair suture passed through a fold of skin in each lid to protect it from the antiseptic lotions. An incision is made from above the upper border of the root of the zygoma straight down in front of the tragus as far as the angle of the jaw, where it turns forwards just below the lower border of the jaw as far as the facial artery. The triangular flap thus marked out is turned forwards and upwards, until the anterior border of the masseter is reached. The edge of the parotid gland and the lower border of Stenson's duct are then defined. The masseteric fascia is divided transversely between Stenson's duct and the highest branch of the facial nerve; then the

edges of the fascia being held apart with retractors, the masseter is divided in its posterior two-thirds. Bleeding is arrested by the application of hot lotion and during the deeper parts of the dissection the wound should be illuminated with an electric light worn on the forehead.

The periosteum is next separated from the exposed portion of the jaw, and the sigmoid notch, posterior border of the coronoid process and the neck of the jaw defined. The notch is enlarged downwards as far as the dental foramen by taking out a small ring of bone with a trephine over the position of the foramen, and then cutting away the bridge of bone which remains between the sigmoid notch and the trephine hole with bone forceps. The position of the foramen is indicated in the adult by a point from 12 to 15 millimetres below the sigmoid notch. Horsley recommends that before applying the trephine the lines to which the bone forceps will be applied should be marked by a series of drill-holes just penetrating the bone. On dividing the periosteum on the inner surface of the jaw the inferior dental nerve and artery are seen. The nerve is secured by a silk ligature and divided at the dental foramen. By the use of narrow retractors the nerve may be traced up behind the border of the external pterygoid muscle and again divided a short distance below the foramen ovale. The lingual nerve which lies half an inch internal to, and a little in front of, the inferior dental, may be similarly treated. It may be found necessary to divide the internal maxillary artery between two ligatures.

In three cases in which recurrence of the pain occurred after the inferior dental nerve had been excised in the manner above described, Horsley has exposed the foramen ovale by a modification of the Pancoast-Salzer operation. A flap is turned down from the temporal region as far as the zygoma; the latter is divided and turned downwards with the masseter; the upper part of the coronoid process together with the lower part of the temporal muscle is removed; and, finally, by detaching the external pterygoid muscle from the sphenoid with an elevator the foramen ovale is exposed. In two cases Horsley "proceeded with a suitable long-handled trephine to remove the bottom of the middle fossa of the skull between the foramen ovale and the foramen rotundum," and severed the branches of the fifth nerve within the skull and removed them freely outside. In the third case the skull was not opened but the nerve was removed from the foramen ovale. In two of these cases the result was satisfactory, but in the third case the pain recurred in the distribution of the first division.

As a last resource in some forms of trigeminal neuralgia in which all other operative measures have failed, excision of the Gasserian ganglion has been practised. This formidable operation was first undertaken by William Rose in 1890. He reached the ganglion by trephining the base of the skull at the position of the foramen ovale. The foramen is exposed by turning the zygoma with the masseter downwards, the coronoid process and temporal muscle upwards, and separating the external pterygoid from the sphenoid. After applying the trephine around, or in front of, the foramen ovale, the ganglion is removed with a specially made cutting hook. The first two patients operated upon by Rose were free from pain after twenty-two months and twelve months respectively. Hartley and Krause have reached the ganglion by turning down a flap of scalp and bone from the temporal region. Horsley, who believes complete extirpation of the Gasserian ganglion to be impossible

on account of its intimate relation with the wall of the cavernous sinus, has in one case practised avulsion of the fifth nerve from the pons. The nerve was reached by turning down a large temporal flap, cutting away the squamous portion of the temporal bone, opening the dura mater and raising the temporal lobe of the brain with a broad copper retractor. The patient, who was much weakened by the prolonged pain, died of shock seven hours after the operation.

Keen has collected 40 cases in which the Gasserian ganglion has been removed up to 1894; the table includes Horsley's case in which the nerve was divided behind the ganglion. Of these cases six were fatal.

The desperate condition of a patient suffering from the most severe form of trigeminal neuralgia justifies any operation which, without grave risk to life, offers any reasonable hope of relief. The results of the extreme measures above described have so far been encouraging, although from the extreme difficulties presented they are hardly likely to be undertaken except by the most dexterous operators.

There is one form of neuralgia of the dental nerves that is so severe and so persistent in its duration, and so paroxysmal in its attacks, that it constitutes a true *Tic*. I have most frequently met with it in the lower jaw, and more commonly in women than in men. It occurs in people who have lost teeth; and the pain, which is excessively acute, commences in the contracted alveoli and the indurated gum covering them. It appears to be owing to the compression of the terminal branches of the dental nerves by the contraction upon them of the empty alveoli. Taking this view of the pathology of this form of neuralgia, I have treated it by the removal of a portion of the indurated alveolar border and gum. Some years ago I did this by removing a V-shaped piece of the bone by means of a Hey's saw; and more recently, I have in addition clipped away the bone by means of cutting pliers. Gross, who has directed attention to this form of neuralgia, uses the pliers only for the removal of the affected bone. In any case it is necessary to cut into, but not through, the body of the bone. By this incision, the dental canal may be opened in the body of the bone, and the nerve destroyed by means of the galvanic cautery.

#### MUSCULAR TIC.

Muscular tic of the face or "**histrionic spasm**" consists of almost constant twitching of the muscles of the face, sometimes so severe as to interfere with sleep, and always causing most serious annoyance and discomfort to the patient. During recent years, the facial nerve has been stretched for relief of this affection in several cases. Godlee has collected 13, including 2 of his own. Keen has increased the number to 21. Of these 1, under the care of Southam, remained perfectly well five years after the operation; 4 were "improved" two years after, and 6 at periods varying from one year to three months; 1 experienced some relief, and in 6 the operation failed completely. In the remaining 3 the result was not certain. The operation causes at the time complete paralysis of the face, which may last from a few hours to three months according to the force used in stretching, and in every case except Southam's some return of the twitching has taken place when the nerve recovered its function. The operation is performed by making a slightly curved incision immediately behind the ear, reaching from the root of the mastoid process nearly to the level of the angle of the jaw. A small

transverse incision should also be made just below the pinna. The anterior border of the process and the edge of the tendon of insertion of the sternomastoid are carefully cleaned, and the parotid turned forwards. The upper border of the digastric is next found, crossing the wound nearly transversely. The nerve is parallel to this, and according to Godlee it will be found emerging from under the middle of that part of the mastoid process which is exposed in the wound. After the digastric is exposed, the dissection must be carried out with a director and forceps as the deep parts of the wound approach the internal jugular vein. When the nerve is found and cleaned, it must be firmly stretched with two blunt hooks. Complete paralysis of the face should result if sufficient force is used.

#### TRAUMATIC PARALYSIS.

Traumatic paralysis is referable to three distinct sets of causes. First, it may arise from *Injury to, or Compression of the Brain* giving rise to localized paralysis when the cortical motor centres are injured, or to hemiplegia or more general paralysis when the deep centres are implicated, or pressure is exerted on the brain substance generally. These conditions have already been fully described in the Chapter on the Injuries of the Head (Vol. I., pp. 744 and 753). Secondly, it may arise from *Injury of the Spinal Cord* giving rise primarily or secondarily to lesion of the substance, either by laceration, compression, or ultimate disintegration. The effects produced will vary with the extent and seat of the injury, from complete paraplegia with loss of sensation in the paralysed parts, to irregular impairment of sensation and motion. (See Wounds of the Spinal Cord, Vol. I., p. 802, and Intraspinal Haemorrhage, p. 789.) Thirdly, *Injury to the Nerves* at any part of their course, from the roots to the terminal subdivisions of their trunks, may occasion paralysis of the parts supplied by them. The effect produced may be immediate, as from Section of a Nerve (see Vol. I., p. 492); or more gradual, from Pressure (see Vol. I., p. 491); or it may occur as the result of Chronic Neuritis following a strain, or other injury (see Vol. I., p. 497).

These conditions having already been fully described, it only remains to notice here a form of paralysis that is occasionally confounded with the traumatic varieties; viz., that arising from exposure to cold, or rheumatic paralysis.

**Rheumatic Paralysis, or Paralysis from Exposure to Cold** (Duchenne), is rare. Duchenne states that he has met with it in most of the nerves of the limbs, and it is far from uncommon in the facial nerve. It most frequently arises from exposure of the affected part to a draught or prolonged chill while the body is sweating. It is difficult to assign a distinct pathological cause for it; that it is due to an actual inflammation of the nerve, a neuritis, may be assumed from the symptoms, and the paralysis is probably the result of compression of the fibres of the nerve from effusion into its sheath. The paralysis may arise in two ways. In the first variety there is prolonged evidence of neuritis before the loss of power appears. The first symptom when a compound nerve is affected is pain along its course, gradually increasing in severity, stabbing or violently aching in character. With this there may be various modifications of sensation in the parts supplied by the nerve, as numbness, tingling, or hyperæsthesia. These symptoms are

increased by movement. After lasting some time, even for weeks or months, the pains cease, and the muscles supplied by the nerve become paralysed, and after a time waste, and then electrical irritability becomes impaired.

In the second variety the preliminary symptoms of neuritis are wanting, the paralysis appearing immediately after exposure to cold. This is commonly observed in the facial nerve, or in the musculo-spiral and occasionally in other nerves. Duchenne collected over 100 cases of sudden paralysis of the latter nerve occurring after exposure to cold, usually from sleeping with the arms exposed to a draught. The symptoms of paralysis of the musculo-spiral have already been described (Vol. I., p. 593). Duchenne states that in paralysis from exposure to cold the whole of the parts supplied by the nerve in the forearm are paralysed, whereas in wrist-drop from lead-palsy the supinator longus escapes. In paralysis occurring in this sudden way from cold the electrical irritability of the muscle remains normal, the muscles supplied by the facial nerve alone forming an exception to this rule. This is explained by supposing that this nerve is exposed to more severe pressure when it swells in consequence of its course being through a long canal.

It is important to distinguish these forms of paralysis from that arising from other causes—more particularly from the traumatic forms. This may usually be done by attending to the preliminary history of neuritis in the first form, in which there is also frequently a co-existent or antecedent rheumatic affection of the joints or muscles, and in the second form by the maintenance of the normal irritability of the muscles, remembering, however, that facial paralysis from cold forms an exception to the rule.

The *Treatment* in the early stages is that of neuritis, free counter-irritation and rest, with the administration of salicylate of soda if there are any general signs of rheumatism. When paralysis is clearly developed, faradization must be employed to prevent wasting of the muscles. By these means a cure is always effected, although the recovery is often very slow.

#### NEUROMA.

By **Neuroma** is meant clinically a tumour connected with a nerve. The common neuroma is a fibroma springing from the perineurium. (See, also, Vol. I., p. 1028.) It is composed of dense white fibrous tissue, and as a rule the fibres of the nerve are stretched over it or pass along one side, seldom being involved in the mass.

This tumour may vary from the size of a millet-seed to that of an orange; it is usually solid, but when it attains a large bulk, a cavity may form in it, containing a yellowish or brownish serous-looking fluid, apparently owing to disintegration of the central portions of the mass. In shape it is usually oval or oblong, the long axis corresponding to the course of the nerve (Fig. 421); it grows slowly, and is movable transversely, but not in the direction of the nerve-trunk on which it is seated when that is put upon the stretch by position; it has no appearance of malignancy, and, however large it becomes, it never contracts adhesions to the integument nor involves its structure. Neuroma commonly affects only the nerves of the cerebro-spinal system; but Berard met with one case of the disease on a ganglionic nerve. The series of special sense are very rarely the seat of this disease. Indeed, the

only recorded case with which I am acquainted of a neuroma connected with one of those nerves, is one described by Lidell of New York, of a neuroma of the optic nerve filling up the orbit, flattening and protruding the eye; it was extirpated together with the contents of the orbit.

Most commonly the tumour is single, and is usually painless. As it increases in size it may become the seat of severe lancinating or neuralgic pain, which extends, however, only to the parts below the tumour, and is commonly paroxysmal. The motor function of the nerve is very seldom affected. The pain is evidently due to the stretching of the nerve fibres as they pass over the tumour. Single neuromata are sometimes not only painful but acutely tender when touched; but when many tumours are present it is a singular fact that they are always painless and unattended with any inconvenience except such as arises from their numbers and bulk. The number of such

tumours is sometimes amazingly great: thus, in one of R. W. Smith's cases, described in a monograph which contains a full and accurate account of this disease, he counted in the two lower extremities alone more than 250 of these growths, besides those in other parts of the body. In another case related by him, there were upwards of 200 small neuromata scattered over the sides of the chest and abdomen, 450 on the right lower extremity, and upwards of 300 on the left; altogether probably no fewer than 2000 of these growths in "this unprecedented case." Multiple neuromata are often congenital, and occur in young subjects.

Other tumours besides fibromata are occasionally met with in connexion with nerves. Myxomata are perhaps the most frequent. In 1870 I amputated the leg for a spindle-celled sarcoma of considerable size, which was found on dissection to have sprung from the posterior tibial nerve.

Fig. 421. — Neuroma with Nervous Filaments spread out over Tumour.

Under the name of **plexiform neuroma**, Verneuil has described a very rare form of tumour met with in the subcutaneous tissue, especially in the neck and upper part of the face. It is composed of a group of nervous twigs, thickened by a fibrous growth in the epineurium. The

twigs are convoluted, twisted in all directions, and nodular, and are held together by loose areolar tissue. It is probably always of congenital origin. According to Gowers about twenty cases have been recorded.

The **painful subcutaneous tubercle** (see Vol. I., p. 1022) is probably also a fibroma connected with a nervous twig.

**Traumatic Neuromata** may arise from the wound or partial division of a nerve. The central end of every divided nerve becomes more or less bulbous, the enlargement being composed partly of dense fibrous tissue and partly of newly formed nerve fibres. As a rule this condition, which must be regarded as normal, is unattended with any pain or discomfort. Occasionally, however, the enlargement reaches the size of a nut or pigeon's egg, and then the growth must be regarded as a true tumour. It may be acutely tender and give rise to the most intense neuralgic pain.

*Treatment.*—No neuroma should be interfered with unless it is causing inconvenience by the pain it gives rise to or by its bulk. If it becomes neces-

sary to do something to relieve the patient, excision of the tumour is the only possible mode of treatment. In idiopathic neuromata an attempt must always be made, by cautious dissection, to remove the tumour from the nerve, without cutting this across. This can be done in most cases without difficulty. If it is impossible to save the whole trunk, a few fasciculi may possibly be preserved which will maintain the continuity of the nerve and facilitate subsequent restoration. If complete division is unavoidable, an effort must be made to suture the divided ends after relaxing the parts as much as possible by position. If this be found impracticable on account of the length of nerve excised, the ends should be approximated as nearly as possible by several catgut sutures.

Two methods deserve further trial in cases in which as the result of injury or the removal of a tumour an extensive gap is left in a nerve: viz., nerve grafting; and suture of the distal end of the divided nerve into the trunk of a neighbouring uninjured nerve. The results of filling the gap by a piece of nerve taken from an amputated limb or from one of the lower animals have been very variable. In a case recorded by Mayo Robson an interval of two inches in the median nerve resulting from the removal of a neuroma was filled by a piece of the posterior tibial nerve of an amputated leg. Recovery was complete at the end of five months. It is doubtful whether the engrafted segment serves any other purpose than to guide the newly-formed nerve fibres from the upper to the lower portion of the divided trunk.

The other method consists in carefully adjusting the distal end of the divided nerve by means of fine sutures to the trunk of a neighbouring nerve. Partial success has been recorded after this treatment.

Traumatic neuromata of stumps are treated by excision.

## CHAPTER XXXIX.

## DISEASES OF THE LYMPHATIC SYSTEM.

## INFLAMMATION OF THE LYMPHATIC VESSELS.

**LYMPHANGITIS**, or as it was formerly called, **Angeioloecitis**, is a diffuse inflammation of the lymphatic vessels.

**Causes.**—In the vast majority of cases it arises from the irritation caused by the presence within the vessels of the products of an infective inflammation affecting the tissues from which they derive their lymph. It thus forms rather a complication of these inflammations than an independent disease. Very commonly it is associated with cutaneous erysipelas, but it is also met with in other forms of infective inflammation : thus it is a frequent result of the inoculation of virulent matter from dead bodies, and is occasionally seen in the lymphatics leading from a soft chancre. In most cases, therefore, a wound or abrasion serves as the starting-point of the inflammation. It is very rarely indeed that lymphangitis occurs without some such external cause ; yet I have seen cases in which careful examination has failed to detect any breach of surface or evidence of local infection. The disease is predisposed to by the same causes that favour the development of erysipelas, as by atmospheric vicissitudes, by particular seasons of the year, more especially the early spring, and by epidemic influences. Broken health and the neglect of hygienic precautions also tend to induce it.

**Morbid Anatomy.**—The walls of the inflamed vessel become swollen, softened, and infiltrated with small round cells, and the endothelium desquamates. Tessier states that the lymph coagulates, forming a rosy clot which plugs the vessel. The inflammation, though commencing from irritation within the vessel, soon extends beyond its walls, the surrounding areolar tissue becomes swollen and infiltrated with inflammatory products, and sometimes suppuration may take place around the inflamed lymphatic.

**Symptoms.**—During the progress of an ordinary injury, the patient is seized with chills or rigors, with considerable elevation of temperature reaching 102° or 103° F., attended, perhaps, with vomiting or diarrhoea. These symptoms may precede by twelve or fourteen hours the local signs of the disease, but more commonly they accompany them. On examining the part it will, if superficial, be seen to be covered by a number of fine red streaks, at first scattered, but gradually approximating to one another so as to form a distinct band, about an inch in breadth, running from the part affected along the inside of the limb to the neighbouring lymphatic glands, which will be felt to be enlarged and tender. The band itself feels somewhat doughy and thickened. Sometimes one lymphatic can be felt hard and isolated like a piece of whipcord. There is usually more or less œdema of the limb, from the implication

of the deeper lymphatic vessels and their obstruction by the inflammation. Along the course of the inflamed lymphatics, erysipelatous-looking patches not unfrequently appear, and coalesce until they acquire a considerable size, and constitute as it were a distinct variety of erysipelas. In some cases the glands are affected before any other local signs manifest themselves, owing probably to the deeper-seated lymphatics having been first implicated; or possibly to the direct absorption of, and deposit in them of, some infective matter that constitutes the primary source of the inflammation. Not uncommonly throughout the disease the inflammation continues to be confined principally to this set of vessels, giving rise to great and brawny swelling of the limb, but without much if any superficial redness. The constitutional disturbance which is at first of the active inflammatory type, may gradually subside into the asthenic form.

**Results.**—The disease usually terminates in resolution at the end of eight or ten days. In other cases, localized suppuration may take place, sometimes in the form of one large deep-seated abscess in the iliac fossa or in the thigh if the lower extremity, or under the pectorals and in the axilla if the upper extremity be the seat of irritation; or a chain of abscesses may form along the course of the inflamed lymphatics and in the glands to which they lead. In some instances, after the disappearance of the disease, a state of chronic and rather solid œdema of the part may be left, giving rise indeed to a species of false hypertrophy, and constituting a troublesome consequence. More rarely death results, either from general blood-poisoning, or as the effect of exhaustion from prolonged suppuration of deep-seated abscesses.

The **Diagnosis** of inflammation of the lymphatics has to be made in its early stages from phlebitis and erysipelas, and of the abscesses in later stages from those of pyæmia. From phlebitis it is easily distinguished by the superficial redness of lymphangitis, and the absence of the cord-like plugged vein. From erysipelas it is distinguished by the want of a defined margin to the redness, and by its extending in the line of the lymphatic vessels only; but the affection in some cases is closely allied to erysipelas, and consequently the distinction may be of little consequence. The acute lymphatic abscess is usually distinguished without difficulty from the pyæmic: the lymphatic abscess being, if deep, solitary; if superficial and multiple, confined to the track of the previously inflamed absorbents; in either case being always between the starting-point of the primary source of irritation, or wound, and the glands—in the calf, thigh, or iliac fossa, if the primary irritation be in the lower extremity; in the axilla if in the upper. The fever is moreover more continued, and the severe rigors and sweatings of pyæmia are wanting.

**Treatment.**—It is of the first importance that any focus of suppuration, such as a whitlow, to which the lymphangitis is secondary, be properly treated. In superficial lymphatic inflammation of the skin, the application of belladonna, as recommended by Christopher Heath, is the most efficient agent in subduing the local process; a paste of equal parts of the extract and of glycerine should be thickly smeared over all the inflamed parts, and covered with a thick layer of cotton-wool or a flannel fomentation; the limb at the same time being kept elevated. As an alternative treatment, though of inferior value, hot poppy fomentations may be used. If after the acute inflammation has been subdued, much chronic induration and œdema occur, the use of an elastic bandage and methodical friction will be of service. If abscesses form, they should be

opened early and treated on ordinary principles. The *constitutional treatment* is the same as for erysipelas. No depletion is ever justifiable, and stimulants are often required in considerable quantities, with abundant liquid food of a nourishing kind. Perchloride of iron and quinine are often useful.

#### VARIX OF THE LYMPHATIC VESSELS.

VARIX OF THE LYMPHATICS has occasionally been met with, both in the superficial and deep networks and in the lymphatic trunks. The part most commonly found affected has been the inner side of the thigh; but the disease has also been seen in the anterior wall of the abdomen, about the ankle and elbow joints, and on the prepuce. In the superficial lymphatics, the varix first appears in the form of small elevations, giving the skin an appearance which has been compared to the rind of an orange; it subsequently takes the form of little vesicles covered with a thin layer of epidermis. Varix of the larger lymphatic trunks frequently accompanies the condition just described. The vessels may either be dilated cylindrically into round beaded enlargements, often semi-transparent, and but slightly compressible; or ampullæ may be formed on them, giving rise to soft swellings, fluctuating under the finger. There is some œdema, attributable either to obstruction of the lymphatics or to the impeded flow of the lymph.

In 31 out of 55 recorded cases, a discharge of lymph (**Lymphorrhœa**) has been observed. This has been seen to occur also without varix, as the result of wound. In the latter case, the flow is continuous; while in the lymphorrhœa which attends varix it is to some extent intermittent. The identity of the fluid discharged with lymph has been established by chemical and microscopic examination. An excessive discharge of the fluid is apt to produce symptoms of general debility, of the same kind as those induced by hæmorrhage.

**Treatment.**—Spontaneous cure of lymphatic varix has been observed in cases where the penis was affected, the disease being the result of the obstruction to the flow of lymph caused by buboes. In other instances, various plans of treatment have been tried, with apparently indifferent result. Caustics have been used by several Surgeons, but, as the disease is often deeply seated as well as superficial, with but little effect. Bean treated three cases successfully by introducing a seton into the dilated lymphatic vessels, and exciting adhesive inflammation. B. Bell advised ligature of the lymphatic vessel, from which the discharge of fluid takes place. Compression by means of a bandage has been recommended by Nélaton.

#### ELEPHANTIASIS ARABUM.\*

**Elephantiasis Arabum** is a disease endemic in many tropical and sub-tropical countries, occurring in the West Indies, South America, India, China, Africa and elsewhere. It is very rarely met with in Europe. The disease is characterized by a remarkable enlargement of the affected part, resulting from changes in the skin, subcutaneous tissue and connective tissues generally. It may affect one or both lower extremities, the scrotum or labia, and more rarely, the upper extremities, mamma, or face. When the condition affects

\* For full information regarding this disease, reference may be made to an article by Patrick Manson in Davidson's "Hygiene and Diseases of Warm Climates," 1898.

the lower extremity, the disease has received the name, "**Barbadoes Leg.**" Only a very brief description of its principal features can be given here.

When the disease attacks the lower extremity it is usually confined to the parts below the knee, but the whole limb may be affected. The enlargement of the limb may be enormous, the hypertrophied tissues being thrown into large folds separated by deep sulci. The skin itself is much thickened, and as the result of hypertrophy of the papillæ presents a coarse velvety or warty appearance (Fig. 422).

In elephantiasis of the scrotum the tumour may reach enormous proportions,

Fig. 422.—Elephantiasis Arabum of Lower Limb.

forming a tumour nearly as large as the trunk, and perhaps weighing 70 or 100 lbs., or even, as in one recorded case, as much as 224 lbs. The disease is rarely seen in this country, though Liston once had occasion to remove such a mass weighing 44 lbs. The tumour forms a pear-shaped mass covered with coarse warty skin. The penis is usually completely buried in the upper and front part of the tumour, whilst the testicles lie posteriorly in the lower half. Large hydroceles are usually present. Fig. 423 represents a tumour of this kind, weighing 40 lbs., which was successfully removed by Rogers of the Mauritius. It is taken from a photograph of the case, kindly sent to me by that gentleman. When the disease affects the labia or other parts, the changes produced are similar to those in the lower limbs and scrotum.

**Pathology.**—It has long been supposed that elephantiasis Arabum results from some obstruction to the return of lymph from the affected area, and indeed the enlargement of the part is usually preceded by repeated attacks of lymphangitis attended with fever. The fact that the disease is endemic in certain countries, and even in individual islands and limited districts, suggests

that it owes its origin to some cause which is similarly distributed. Manson has indeed brought forward the strongest evidence to show that the disease results from the presence in the lymphatics of a small nematoid worm—the *filaria sanguinis hominis nocturna*. The adult parasites exist in some part of the lymphatic system, and the embryo filariæ are set free in the lymph, and in many cases enter the blood-stream. Manson has pointed out the remarkable fact that the embryo filariæ are found only in blood drawn during the night, and he has also proved that the further development of the embryos occurs in the body of the mosquito. Amongst the conditions which are undoubtedly caused by this parasite in man may be especially mentioned chyluria, lymph scrotum, and a peculiar form of enlargement of the glands of the groin. In **lymph scrotum** there is some enlargement of the part with general dilatation of the lymphatics, which appear as “herpes-like vesicles,”

Fig. 423.—Elephantiasis of the Scrotum.

or larger “ampullæ,” from which a clear or milky fluid escapes. An explanation of these conditions is probably to be found in an obstruction of the thoracic duct with consequent regurgitation of chyle into other lymphatic channels. In some cases of lymph scrotum and other local forms of lymphatic enlargement the fluid which escapes is clear and no filariæ are found in the blood. Embryo filariæ are, however, found in the lymph and in addition free ova which are supposed to block the lymphatic glands and so cause the dilatation of all the lymphatic vessels behind the obstruction. Of the many arguments which Manson has adduced to prove the filarial origin of elephantiasis Arabum may be especially mentioned:—

1. The geographical distribution of the parasite and the disease correspond.
2. The history of many cases of elephantiasis of the scrotum suggests that it began as a lymph scrotum.
3. Elephantiasis is frequently associated with other diseases known to be caused by the filaria. The absence of filariæ from the blood in most cases can be explained by supposing that the glands receiving the lymphatics of the affected region are completely blocked.

**Treatment.**—The treatment of elephantiasis of the leg is unsatisfactory, but considerable relief can be afforded by elevation of the limb and the application of an elastic bandage. In severe cases it has been recommended to diminish the supply of arterial blood to the limb by compression of the femoral artery as first suggested by Dufour, or by ligature of the vessel as recommended by Carnochan. In certain cases some improvement has followed both these methods of treatment, but at the present day they seem to have been generally abandoned. Manson states that he has several times dissected off strips of the thickened skin, in the direction of the long axis of the limb, with the object of diminishing the bulk of the limb and of preventing further enlargement by the contraction of the resulting cicatrices. In extensive cases of elephantiasis of the scrotum removal of the part may very

successfully be practised. In performing the operation, two points demand attention. The first is the avoidance of hæmorrhage, which in so vascular a region might easily be fatal. The other is the preservation of the penis and testes.

The avoidance of hæmorrhage may be effected by various methods, which may be employed singly or combined. The loss of blood may be greatly diminished by position, as originally advocated by O'Ferrall in 1844, the patient lying on his back and having the tumour raised above the level of the body for an hour before the operation. The tumour may at the same time be bandaged so as to compress its vessels, and thus empty them. This method does not affect the proximal hæmorrhage, which may be prevented by one of the following methods:—1. The application of the aortic compressor; 2. Esmarch's bandage; 3. The application of a screw compressor to the root of the tumour. Either of these methods may be conjoined with position.

The use of the compressor is especially advocated by Dr. Turner, a medical missionary at Samoa, who has removed no fewer than 138 of these tumours. The clamp used by Dr. Turner consists of two parallel bars of sufficient length, united by two long upright screws worked by nuts. After the tumour has been raised and emptied of its blood, the compressor is applied to the neck and screwed down tight, when the operation is proceeded with.

The directions given by Dr. Turner for the safe performance of the operation are as follows:—The patient having been anæsthetized, the clamp applied, and the tumour emptied of its blood by pressure, the clamp must be screwed home. The tumour, if small, may then be raised with the hands; if large, two strong hooks should be passed deeply into the leathery skin at the bottom, and being attached to a block and tackle fixed to the ceiling, the whole mass must be raised so that its posterior part is brought into view. A couple of skin flaps about  $1\frac{1}{2}$  inch long are then made here at its neck. The tumour is then lowered and allowed to fall forward. Two or three skin flaps are now to be made from the front and sides of the tumour, the front flap being intended to cover in the penis when dissected out: one should be of sufficient size for this purpose. The lateral flaps are intended to cover in the testes. The penis must next be sought for. In small tumours where it lies superficially, it is easily found. In larger ones where deeply buried, it is best reached by slitting up the aperture through which the urine escapes, going in search of the glans penis, and then dissecting out the organ, which should be held up against the abdomen. The testes are next to be sought for by cutting diagonally, and with finger and knife they must be cleared and the cords followed up. By a few strokes of the knife the mass is then removed. A large number of vessels—from 30 to 40—may require ligature in the stump; they are tied as the clamp is gradually loosened. The skin flaps are then brought together over the penis and testes, and the wound treated on ordinary principles. Some Surgeons object to the formation of skin flaps with the view of covering in the penis and testes, as tending to favour recurrence of the disease. But as Dr. Turner very truly remarks, the skin on the neck of the tumour is generally healthy, being merely dragged down from the parts above the scrotum.

## LYMPHADENITIS, OR INFLAMMATION OF THE LYMPHATIC GLANDS.

ACUTE INFLAMMATION OF THE LYMPHATIC GLANDS almost invariably results from the irritation of some noxious material conveyed to them by the lymphatic vessels. The lymphatics through which it passes on its way to the glands may themselves be inflamed, but more frequently they escape. This fact would seem to indicate that in the majority of cases the irritating matter is particulate and not in solution, for we know from experiment that solid particles pass readily through the lymphatic vessels, but are arrested in the glands. In every acute inflammation the quantity of lymph passing through the glands in connexion with the affected area is greatly increased. In simple inflammations in a healthy subject this causes slight swelling, which subsides as soon as the cause is removed; but in scrofulous subjects, as before pointed out, there is a peculiar tendency to inflammation of the lymphatic glands from slight causes, and in them the swelling may persist and may pass on to suppuration or chronic inflammation. In infective inflammations the inflammatory products contain the special virus to which the inflammation is due, and this being carried by the lymph-stream to the glands may excite a similar process in them. Most specific inflammations are accompanied by the presence of definite microscopic organisms in the exudations, and in such cases the organisms can frequently be demonstrated with the microscope after death in the lymphatic glands nearest to the seat of the disease. As a rule the secondary inflammation in the glands closely resembles in character that at the primary seat of disease. Thus, in cutaneous erysipelas, the glands are invariably swollen and tender, but seldom suppurate; in soft chancres, suppuration commonly takes place; and in diphtheria, the glands are always enlarged and painful, but pus rarely forms, while in scarlet fever suppuration is often very troublesome. In syphilis, the change that takes place in the lymphatic glands is identical with that occurring at the seat of inoculation; and the same is the case in secondary tuberculosis.

Some infective inflammations, as hospital gangrene and phlegmonous erysipelas, have but little tendency to infect the glands. This is possibly due to coagulation of the lymph in the spaces of the inflamed area.

In the majority of cases there is no difficulty in discovering the source of the irritation which has caused the glands to inflame. In scrofulous subjects, however, the effect may be produced by causes so comparatively slight that their detection becomes proportionately difficult. In some cases it appears to arise simply in consequence of a strain, as from over-walking. In children the glands are more prone to suppurate from slight sources of irritation during convalescence from measles or some other acute specific disease.

**Pathological Anatomy.**—In *acute* inflammation the gland is swollen, and at first pink in colour and soft. At a later stage yellow points of commencing suppuration will be observed, both in the medullary and the cortical part. At a still later period the greater part of the gland may be hollowed out into a cavity filled with pus. The appearances of *subacute* inflammation are much the same as in the acute. The microscope shows the usual changes observed in all inflammations; the vessels are distended, and the gland is crowded everywhere with multitudes of small round cells. These very early choke the lymph-sinuses. As these cells exactly resemble the normal corpuscles of the gland, it is impossible to determine whether they are formed by multiplication

of the normal lymphoid cells, or have been brought to the gland with the lymph from the inflamed area, or have migrated from the vessels. The capsule and trabeculae are similarly infiltrated with small cells. The formation of pus takes place in the same way as in other parts. In the less acute forms larger cells are found, formed by proliferation of the flattened corpuscles that cover the trabeculae and the inner aspect of the capsule. In the more acute forms the surrounding tissues are early implicated in the inflammation.

**Symptoms.**—In **Acute Lymphadenitis** there are pain, swelling, and tenderness, and stiffness about the affected glands, with a dull heavy sensation in them. The outline of the swollen gland is at first clearly defined, but soon becomes concealed by the inflammation extending to the contiguous areolar tissue. Before long redness, oedema, and the other signs of acute abscess make their appearance. In **Subacute Lymphadenitis** the glands become swollen, enlarged, and tender, and are matted together by inflammatory exudation into the surrounding tissues. If an abscess form, it frequently commences in the structures around the glands; and those are perhaps eventually exposed at the bottom of the cavity that results. This is especially apt to happen in cachectic and strumous persons from slight sources of irritation. Very commonly in such subjects the inflammation of the glands runs into a chronic state.

**Treatment.**—The local treatment of inflamed lymphatic glands varies according to the nature of the process. In all forms the local irritation to which the inflammation is due must if possible be removed. In *acute lymphadenitis* the application of glycerine and extract of belladonna in equal parts, and hot fomentations may prevent suppuration. In the *subacute* condition, spirit lotions containing iodide of potassium will sometimes subdue the inflammation and take down the swelling. If an abscess form, it must be freely opened and the part dressed with some antiseptic application. The sinuses which are often left when the abscess is imperfectly opened, or allowed to discharge by itself, require to be treated by stimulating applications, especially the nitrate of silver; but very commonly they will not heal unless they are laid open, scraped, and dressed from the bottom.

**CHRONIC LYMPHADENITIS. TUBERCULOUS DISEASE.**—Chronic inflammation of the lymphatic glands may arise as a sequence of subacute inflammation, but more commonly the glands gradually enlarge without marked pain or tenderness in consequence of chronic irritation of some kind. It is often impossible to make any accurate distinction clinically between simple chronic inflammation, strumous enlargement, and tuberculous disease. Chronic inflammation of the glands is commonly looked upon as the most marked characteristic of the strumous diathesis, and the relation of the process to tubercle has already been sufficiently discussed. In an otherwise healthy individual prolonged local irritation of the skin or mucous membrane will cause a chronic inflammatory enlargement of the neighbouring lymphatic glands. In a strumous subject the amount of glandular enlargement may be out of all proportion to the local irritation causing it. Such strumous glands are not necessarily tuberculous, but are already rendered favourable sites for the growth of the tubercle bacillus, should the latter reach them through the lymphatics, to which it probably gains an entrance by way of the unhealthy mucous surface which first caused the glandular enlargement. In many cases, however, no source of infection can be detected. Tuberculous disease of

lymphatic glands may also occur secondarily to some primary tuberculous lesion elsewhere. Thus, for example, the gland above the internal condyle of the humerus is not unfrequently infected in cases of tuberculous caries affecting the bones of the hand or fingers. In some rare instances the lymphatic vessels between the primary focus and the secondary deposit in the glands are themselves similarly diseased. Finally, in some cases of general tuberculosis the lymphatic glands may be the seat of miliary tubercles.

**Symptoms.**—Tuberculous disease of lymphatic glands occurs principally in children and young adults. Any gland may be affected, but those with which the Surgeon most often has to deal are the glands in the neck, especially those in the submaxillary region and the *glandulae concatenatae*, and sometimes the axillary and inguinal glands.

The glands slowly increase in size, at first remaining clearly defined and distinct from each other. They may after a time cease to enlarge, and remain permanently without further change, but more commonly after continuing in this state a variable time they soften.

Fig. 424.—Tuberculous Glands of Neck.

The inflammation then extends to the surrounding tissues, and the glands become adherent to neighbouring parts, and finally to the skin. Several glands may thus become fused together, forming a large indurated and nodulated mass (Fig. 424). Suppuration takes place slowly, and the skin becomes thin, blue, and undermined. Finally, it gives way by a small opening, and curdy pus is discharged, mixed with the *débris* of the softened cheesy matter from the gland. The discharge may continue for weeks or months, being kept up partly by the gradual expulsion of the remains of the degenerated gland, and partly

by the thinned and undermined skin being too feeble to take any part in healthy repair. The opening may close for a time, bursting open and discharging again at intervals. In other cases the thinned skin perishes, and the remains of the gland may be exposed as a reddish-grey or fleshy mass protruding in the midst of the sore. When these sores finally heal, they leave thin blue cicatrices ultimately forming irregular puckered scars.

**Pathological Anatomy.**—A lymphatic gland affected by a simple chronic inflammatory process is often enlarged to many times its normal size. It is usually more opaque than natural, and of a grey or dull pink colour. The consistence varies; in many cases the gland is softer than natural, but not uncommonly it is indurated, as the result of thickening of the trabeculae and capsule and of the meshes of the retiform connective tissue.

Microscopic examination of glands thus affected shows a great increase in the lymphoid corpuscles, not only in the follicles of the gland, but also choking the lymph-sinuses. Amongst the new corpuscles larger cells are found many times the size of a lymph-corpuscle, and apparently developed from them, as

all intermediate varieties are found between the two forms. The flattened cells covering the trabeculæ, and lying on the meshes of the reticulum of the gland, proliferate, and may sometimes be recognized forming a coarse network amongst the lymphoid corpuscles. At first the gland is more vascular than natural, but from the pressure of the accumulated cells the vessels soon become obliterated, and non-vascular areas are formed.

By naked-eye examination alone it may be difficult or impossible to decide whether the condition is one of simple chronic inflammation or of an early stage of tuberculous disease. The first definite evidence of the latter is usually the presence of grey or yellow tubercles dotted about in the gland tissue. We have already seen that the tubercle is commonly deposited in glands already chronically inflamed; if, however, the gland is affected secondarily to a tuberculous disease of the region from which it receives its lymph, it is probably tuberculous from the beginning. Small caseous points soon appear, and these may gradually increase in size, and coalesce till the whole gland becomes a uniform caseous mass still enclosed in the capsule, which is often considerably thickened. The caseation may terminate the process, the cheesy mass remaining dry and encapsuled without further change. In other cases it is followed by a deposit of lime salts, and the diseased gland forms a hard calcareous mass. These formations most commonly occur in the glands of the abdomen and thorax. In superficial glands the caseation is more commonly followed by softening of the cheesy mass, which breaks down into a thick fluid not unlike clotted cream. The softening is accompanied by inflammation, and the slow formation of pus in the tissues round the gland, the capsule gives way at the most superficial part, and the fluid gradually approaches the surface. The chronic abscess thus formed is very slow in perforating the skin, often undermining it for some distance before finding an exit. Microscopic examination in the early stages shows the usual structure of tubercle; small non-vascular areas are seen consisting of giant cells, epithelioid cells, and lymphoid corpuscles.

The caseation commences in the non-vascular spots, and gradually extends. The trabeculæ disappear last in the caseating process. In a considerable proportion of cases the tubercle bacillus can be found in the cheesy glands. The softened caseous product of tuberculous lymphatic glands has long been believed to be a source of general infection, the fine granular *débris* entering the circulation and lodging in distant parts, and there causing the growth of tubercle. Koch's discovery of the bacillus of tubercle showed that in these cases the bacilli or their spores are the actual infective material. This general infection when it does occur is however merely an accidental occurrence, the vast majority of patients who suffer from caseating lymphatic glands escaping with nothing more than the local disease.

In whatever way occurring, inflammation of the lymphatic glands always causes obstruction to the flow of lymph through them, and if the whole or the greater part of the glands of a limb be affected, œdema, often of a solid character, may occur in the parts from which they receive their afferent lymphatic vessels.

The **Diagnosis** of tuberculous disease of the lymphatic glands is rarely attended with difficulty. From *simple chronic inflammation* the distinction may in the early stages be impossible; but the progressive enlargement and the occurrence of softening will usually, sooner or later, reveal the nature of the

disease. From *lymphadenoma* the distinction is likely to be difficult only when a single group of glands is affected. Under these circumstances the character of the glandular enlargement is usually sufficiently distinctive. In tuberculous disease the glands rarely reach a large size before softening occurs, and as the result of surrounding inflammatory changes the individual glands become adherent to one another and to the surrounding structures; in lymphadenoma the individual glands often reach a large size, whilst still showing no evidence of softening and no tendency to become adherent to one another or to the parts around. The diagnosis of a mass of tuberculous glands from a *sarcomatous growth* is usually easy.

**Treatment.**—In the treatment of chronic inflammation of lymphatic glands the first endeavour of the Surgeon should be to remove any source of irritation which may be present. Thus, in the case of the neck, special attention must be paid to the condition of the throat and teeth; the removal of enlarged tonsils and the extraction of decayed teeth being often followed by rapid disappearance of the glandular swelling. Chronic suppuration in the middle ear, pediculi capitis and eczema of the scalp must if present receive appropriate treatment. In many cases, however, no local source of irritation can be detected, and the Surgeon is in doubt whether the glandular enlargement is tuberculous or not. Under these circumstances constitutional treatment may be given a fair trial. Sea-air and a course of cod-liver oil, combined if need be with steel wine, or the syrup of the phosphate of iron, will often prove most beneficial. Local applications are rarely needed, but sometimes methodical friction with iodine or iodide of potassium ointment, or painting the part with tincture of iodine will aid absorption.

Should these methods of treatment fail, the probability is great that the glands are actually tuberculous, and in favourable cases excision may be practised before they have become so adherent as to make complete removal impracticable. By this treatment the Surgeon hopes to avoid disfigurement by irregular cicatrices, to diminish the tendency of the disease to spread to neighbouring glands, and possibly to prevent general tuberculous infection. The most favourable cases for excision are those in which only a single group of glands is affected and is still freely movable on the parts around.

Such a condition is frequently met with in the submaxillary region and posterior triangle of the neck, and in the axilla. Incisions in the neck should be made as far as possible in the natural folds of the skin of the part, the most frequently useful being those made parallel to the border of the lower jaw and along either border of the sterno-mastoid. The operation often resolves itself into a much more extensive dissection than was anticipated, and important vessels and nerves in the neck are often freely exposed. The internal jugular vein is particularly likely to be wounded, and in removing glands from the posterior triangle the spinal accessory nerve must be carefully preserved.

Complete excision is often possible even though the glands have extensively softened. The operation is, however, necessarily more difficult on account of the inflamed condition of the surrounding tissues. Great care must be taken to keep close to the capsule of the gland during its removal lest important structures be wounded. If the gland cannot be completely removed it should be scraped out as thoroughly as possible with a sharp spoon (Fig. 96, Vol. I.). Even under these circumstances complete primary union of the wound may be aimed at.

In some cases a softened gland may conveniently be treated by the following simple method. The gland is steadied between the finger and thumb of the left hand, and a puncture made into it with a scalpel about a quarter of an inch in width. A probe may then be passed along the scalpel, so as to serve as a guide to the opening in the capsule. The scalpel is then withdrawn, and a small sharp spoon passed along the probe into the gland. By forcibly squeezing the gland and scraping with the spoon, the whole of its caseous contents can usually be removed without difficulty. A very fine drainage-tube may be inserted for a few days, after which healing will probably take place without difficulty. The results of this little operation are very much better if strict antiseptic precautions are observed; for if the cavity becomes filled with decomposing discharges, troublesome diffuse suppuration in the areolar tissue may follow. Iodoform or salicylic wool forms the best dressing in most cases. If several glands lie close together, it is sometimes possible to scrape more than one from a single opening in the skin. The scars left after this mode of treatment are very slight.

In many cases, however, a superficial abscess has already formed when the case first comes under treatment. The abscess must then be freely opened and scraped and the edges of the incision held apart with blunt hooks. By careful examination a small track will now often be found passing through the deep fascia to the caseous gland which lies beneath it. The track must be sufficiently enlarged to allow the diseased gland to be thoroughly scraped away with a sharp spoon. This procedure is most important for, as Teale has pointed out, if the superficial abscess only be opened the primary cause of it still remains.

The sinuses and ulcers left by the bursting of chronic glandular abscesses must be treated by free scraping and disinfected with chloride of zinc (40 grains to the ounce) and iodoform. All blue undermined skin should be cut away with scissors, as it delays healing and is itself useless for any purposes of repair. In the case of extensive sinuses in the neck, there is no doubt, as Treves has especially urged, that the constant movement of the part delays healing. Sufficient rest is, as a rule, obtained by a firmly-applied wool dressing, but the use of a leather collar may sometimes be helpful.

#### LYMPHADENOMA.

This disease has already been described in the Chapter on Tumours (Vol. I., p. 1029), and but little remains to be said concerning it. When the disease is apparently limited to a single group of lymphatic glands, the question of their removal often comes before the Surgeon.

If the tumour be large and single, or composed of an agglomeration of multiple masses, and so situated that it can be taken out with safety, its removal is proper, and should be practised. I have several times removed large lymphadenomata from the axilla and upper part of the neck with great advantage. Even when the disease is multiple, single large masses that are sources of special trouble should be dissected out. In one such case a tumour, which was as large as a man's fist, was removed, in University College Hospital, from the axilla. The patient, a delicate woman, had a group of similar growths in the neck, which had remained stationary for twenty years.

The operation should not be undertaken when the patient is very weak or anæmic, more especially when there is persistent elevation of temperature.

The accompanying figure (Fig. 425) from a patient under the care of Christopher Heath is a good illustration of the appearances produced by this disease when affecting the glands at the root of the neck.

With the exception of lymphadenoma, the lymphatic glands are singularly exempt from the growth of primary tumours. Round-celled sarcoma is said

Fig. 425.—Lymphadenoma of Glands at Root of the Neck.

to be met with occasionally, but it is probable that some of the tumours formerly described under that name would now be classed as lymphadenomata. Secondary tumours are, however, extremely common. All forms of cancer tend to affect the glands at an early period of their growth. Round-celled and melanotic sarcomata also frequently give rise to secondary tumours in the glands.

## CHAPTER XL.

## DISEASES OF VEINS.

## VENOUS THROMBOSIS.

THROMBOSIS or coagulation of the blood in the vessels during life is very common in the veins.

**Causes.**—The exact nature of the process of coagulation of the blood is still far from being fully understood. The view generally entertained at the present time is that fibrin does not exist as such in the blood, but is formed from two substances, fibrinogen and fibrin-ferment. The fibrinogen is contained in the blood-plasma in solution. The fibrin-ferment is not supposed to be present in a free state in the blood as it circulates in the body, but is liberated from some of the colourless corpuscles under certain conditions. Blood, in contact with the walls of vessels which, to use Cohnheim's expression, are in a state of "physiological integrity," shows no tendency to coagulate, but when it is brought in contact with dead matter clotting takes place. In the same way, if the integrity of the vessels is damaged by disease or injury fibrin becomes deposited at the damaged spot. The presence of free ferment in the blood may also cause coagulation in the living body. Köhler has shown that if a sufficient quantity of fibrin-ferment be experimentally introduced into the blood-stream, rapid coagulation will take place, even in contact with healthy vessels. If a smaller quantity is injected there is severe febrile disturbance, but thrombosis does not take place, the influence of the healthy walls of the vessels being then supposed to be sufficient to arrest coagulation until the ferment is eliminated from the blood. Other substances have been shown to be capable of causing extensive coagulation in the living vessels. Thus Wooldridge showed that a phosphorized fat known as lecithin, which may be obtained from the lymphatic glands, testis, brain, and other tissues, causes rapid coagulation and death from cardiac thrombosis if injected into the blood-stream. On the other hand, if peptones be injected into the blood-stream during life, blood drawn shortly afterwards fails to coagulate. These observations show that the coagulability of the blood may be directly influenced by the admixture of various foreign substances with it.

Retardation, or arrest of the blood-stream, acts as a powerful predisposing cause of thrombosis. These conditions apply equally to all vessels, whether arteries, capillaries, or veins, but we have to consider them here in reference to the veins only.

The causes of venous thrombosis may be thus classified :—

1. Changes in the condition of the wall of the vessel due to (a) injury ; (b) inflammation ; (c) degeneration.

2. Altered conditions of the blood in which there is supposed to be a liberation of the ferment.

3. Retardation or arrest of the blood-stream : due to (a) diminished *vis a tergo* ; (b) pressure on the vessel ; (c) interruption of its continuity ; (d) obstruction by a thrombus due to any of the preceding causes.

1. **Changes in the wall of the vessel.**

a. *Injury*.—The effect of any severe injury to the coats of a vein is either to extinguish the vitality of the injured parts or so far to diminish it that the vessel wall behaves towards the blood as a foreign body, and a conglum is formed on the damaged part just as it would be on a piece of wire introduced into the vein. A vein is occasionally penetrated by a foreign body, as when a ligature is accidentally passed through it in tying a contiguous artery. Under these circumstances a clot will quickly form upon the foreign body.

b. *Inflammation*.—It has already been pointed out in the Chapter on Inflammation that the most essential feature of the process is a diminished vitality of the affected part to a degree short of actual death. If the inflammation is sufficiently intense the wall of an inflamed vein behaves towards the contained blood as if it were dead matter, and coagulation consequently takes place. Thrombosis thus forms a marked feature of all forms of phlebitis. The causes of inflammation of veins will be described later on (see Phlebitis).

c. *Degeneration*.—Degeneration of the coats is less marked in the veins than in the arteries. In varicose veins, the middle coat is greatly thickened by the growth of fibroid tissue, and calcareous plates are sometimes met with in it ; but the endothelial lining is usually intact, and consequently thrombosis comparatively seldom takes place as a consequence of this alone.

2. **Altered Conditions of the Blood.**—The exact nature of the changes of the blood that predispose to thrombosis is very imperfectly known. The experiments before alluded to show that an excess of free ferment in the blood may act as a powerful predisposing cause, or even the sole cause of coagulation. In septicæmia, pyæmia, and many other acute febrile diseases, there is considerable destruction of corpuscles, and very probably in this way ferment is liberated, and it is well known that thrombosis is common in these affections. The mere excess of white corpuscles, such as is observed in leucocythæmia, does not seem to predispose in any great degree to thrombosis. Koch has observed, in pyæmia experimentally induced in animals, thrombosis of small vessels apparently originating in the plugging of the channel by microscopic organisms, and possibly some such condition may be present in some cases of venous thrombosis.

3. **Retardation of the Blood-stream.**—Perfect rest of the blood when withdrawn from the body delays coagulation, and free movement hastens it. It is impossible, therefore, to suppose that retardation or arrest of the flow can act directly as a cause of thrombosis. Nothing, however, is more certain than that it does form one of the most important causes of coagulation in the living vessels. It may act in various ways. First, if the arrest of the circulation be complete and of sufficient duration, the vitality of the part will suffer until the vessels come to act as foreign bodies and coagulation takes place. Secondly, if a part of the vein is already diseased or injured, the retardation of the blood-stream will favour the adhesion of the white corpuscles to the unhealthy surface, which is the first step in thrombosis.

when the blood is still moving. Thirdly, if the blood stagnate for a sufficient time the white corpuscles may perish from want of oxygen and disintegrate, thus liberating the ferment and inducing coagulation. Lastly, it is possible that the nutrition of the endothelium may suffer from arrest of the flow of blood through the vessel even when the circulation through the surrounding tissues is sufficiently active to maintain their vitality.

Retardation or arrest of the blood-stream may arise (*a*) from diminished *vis a tergo*. This may be due to want of power in the heart from old age, bad nourishment, exhausting fevers, or to shock or loss of blood from injury or operation. Interruption to the proper distribution of the force through want of elasticity in the arteries acts in the same way. Obstruction of the main artery of a limb, or arrest of the capillary circulation in the area from which a vein derives its blood, will in like manner retard the venous flow.

(*b*) Another very common cause of retardation or arrest of the blood-stream in the veins is the obstruction caused by the pressure of a tumour, or the contraction following chronic inflammation of the connective tissue of an organ: examples of these conditions may frequently be seen in the iliac veins pressed upon by a pregnant uterus or an ovarian tumour, and in the vessels of a cirrhotic liver; and it must be remembered that a tight bandage may act in the same way.

(*c*) When a vein is divided in a surgical operation, it empties itself and becomes collapsed as far as the next pair of valves, but above these it may remain full of stagnant blood up to the point at which another vein enters the trunk. When a vein is ligatured in its continuity there will be, in addition, stagnation of blood below as far as the next collateral branch.

(*d*) When the circulation is too feeble to press the valves back against the walls of the vessel, or when in consequence of dilatation they are never properly closed, but project into the lumen of the vein, it not uncommonly happens that stagnation takes place in the sinuses of the valves, and small thrombi may thus form, which finally project into the lumen of the vessel, and by gradual increase may at last close it completely.

**The Process of Thrombosis.**—Thrombosis may take place while the blood is moving, the lumen of the vein becoming gradually filled with the coagulum, or while the blood is at rest.

The appearance of the thrombus varies with the conditions under which it is formed, much as the coagulum obtained by whipping blood differs from that formed when freshly shed blood is allowed to coagulate undisturbed in a vessel. The process of thrombosis has been observed experimentally by Zahn in the veins of the mesentery and tongue of the frog. A large vein being chosen, its walls were injured by placing a crystal of common salt near or directly over it. On watching the injured spot, the white corpuscles of the passing blood were seen to adhere to it until they were heaped up, sometimes to such an extent as completely to obstruct the vein. If the injurious action of the salt had not been very severe they might break loose again and pass away into the blood-stream; if it had been more powerful the corpuscles remained adherent. After some hours they were seen to undergo a marked change. The greater part disintegrated, their outline being lost and their nuclei no longer being recognizable; and a fine granular mass, having the appearance of freshly-formed fibrin, appeared in the place they formerly occupied. This observation is in harmony with the view that the liberation

of the ferment by disintegration of the white corpuscles plays an important part in the process of coagulation. The thrombus thus formed was in some cases pure white in colour, but more commonly a few red corpuscles were entangled amongst the white. The more rapidly the plugging of the vessel took place the more red corpuscles were entangled in the thrombus. When coagulation takes place in a vessel in which the flow is completely arrested, the clot differs in no respect from that formed in blood drawn from the body. It entangles in its meshes all the corpuscles, both red and white, and presents the familiar dark red colour.

These observations explain the different appearances of the thrombus under the different circumstances in which thrombosis takes place. The clot formed above an injury which completely obstructs a vein, as when it is divided or tied, is uniform in structure, dark red in colour, and at first but loosely adherent to the inner coat of the vessel. At a later period, as in the case of a ligatured artery, it becomes denser in consistence from contraction, and more firmly adherent, and loses its colour in consequence of disintegration of the red corpuscles. A thrombus formed by gradual deposit from the circulating blood upon the unhealthy walls of a vein is either white or mixed in tint, according to the rapidity with which it is formed. It is firmly adherent to the inner coat of the vein and laminated in structure. Microscopic examination shows it to contain few red disks, but numerous white corpuscles which have escaped disintegration are usually found between the laminae.

As a rule the thrombi arising in cases in which an altered condition of the blood is supposed to be the cause of coagulation are white or mixed, the fibrin being deposited gradually on the walls of the vein, starting from some point where from disease or injury the endothelium is damaged.

When a vein is completely obliterated by a white thrombus, the stagnant blood on each side coagulates, forming a red clot adherent to the white. After death a further extension of this red clot takes place. These *post-mortem* clots are recognised by their softness and by their floating free in the vessel.

Cornil and Ranvier have supposed that in many cases at least the central portion of a laminated clot, and not its peripheral layers, is the oldest, the fibrin having been first deposited on the wall of the vein and then separated from it by contraction, though prevented from passing on towards the heart by the prolongations extending into the collateral branches. This view, however, seems far from probable. The only appearance suggesting such a process is met with in the clots extending from the heart into the pulmonary artery in cases of cardiac thrombosis. These are commonly found to fill the vessel incompletely, and often present perfect casts of the pulmonary valves. In these cases, however, the coagulation takes place immediately before death, and very probably the contraction is *post-mortem*.

The **Fate of the Thrombus** varies according to the circumstances in which it is placed and the causes of its formation. Thrombi arising from injury undergo the same changes as those forming in arteries under similar circumstances (Vol. I., p. 415). The restoration of the channel through a vein, when the continuity of its walls has not been interrupted, takes place more readily than in similar conditions in the arteries. It is possible that in some cases this may result from disintegration of the clot, the *débris* being carried away and lodged in the lungs, where, if non-infective in character, it would cause no serious symptoms. The normal process of restoration,

however, is effected by the clot becoming infiltrated by new cells proceeding from the wall of the vessel, as in the permanent closure of a divided vein. New vessels afterwards penetrate amongst these cells, and by means of these a communication is established between the permeable portions of the vein above and below the clot. The channel, at first small, gradually enlarges by absorption of the tissue through which it passes, and thus, at last, the full calibre of the vein is restored.

*Softening and Disintegration* are common changes when the thrombus has been formed in consequence of inflammation of the vein, or as a result of those altered conditions of the blood which accompany septicæmia or malignant fevers. It is a very frequent occurrence when the affected vein leads from a wound the discharges of which are in a septic state, or from an area affected with some infective inflammation, as in acute necrosis of bone.

Softening most commonly takes place in white or mixed thrombi. It commences in the centre of the clot at the part furthest removed from the walls of the vein. The clot if mixed becomes completely decolorized, and gradually breaks down into a creamy fluid resembling pus in appearance. Microscopic examination, however, shows that it is not pure pus. In some cases it is composed merely of granular *débris*, no corpuscles of any kind being recognizable; in others a certain number of pus cells may be mixed with the *débris*. These are white corpuscles, which were either contained in the clot and have escaped disintegration, or have wandered into it from the surrounding parts. In most cases in which softening takes place, micrococci are found in abundance in the puriform liquid. The effects of the process of softening will be discussed immediately.

*Calcification of a Thrombus* is of rare occurrence. It occurs chiefly in the small clots that form in varicose veins in the pouches behind the valves. These calcified clots form small rounded bodies, varying in size from a mustard seed to a pea, and are known by the name of phleboliths.

**Effects of Thrombosis.**—The first effect of thrombosis when not arising from obstruction is necessarily to arrest the flow of blood through the vein. If a single superficial vein be obstructed, this may cause no marked symptoms; but when the clot is situated in a main trunk, as in the femoral at the groin, it causes great œdema of the parts below. This is commonly seen in the so-called "white leg," which occurs after labour. If the vein remain permanently obstructed, the œdema may subside after some weeks or months, the collateral veins gradually dilating, and the free return of blood thus being re-established. In other cases the œdema diminishes, but does not completely disappear, the limb swelling considerably when in a dependent position. When this occurs, the areolar tissue is indurated, the œdema becoming more "solid" as time goes on. The nutrition of the parts is interfered with, and chronic eczema or ulceration of the skin from slight causes is not uncommon.

The relation of thrombosis to inflammation of the vein is a subject on which there has been considerable difference of opinion. Pathologists in the early part of the century regarded the presence of a thrombus in a vein, except when obviously due to mechanical causes arresting the flow of blood, as evidence of previous inflammation of the coats of the vessel. Some later pathologists on the other hand have maintained that when thrombosis is found associated with inflammation of the coats of a vein, the latter condition is

always secondary to the former. The truth probably lies between the two views. A vein may become inflamed as the result of mechanical violence, or of being laid bare in an operation and subsequently exposed to the contact of decomposing discharges, or by being implicated in unhealthy ulceration of the surrounding structures. In other cases diffuse inflammation may spread from a septic wound in the loose areolar tissue surrounding the vein. In all these conditions the phlebitis precedes the thrombosis. The opposite condition may be met with when a vein has been wounded, and its divided end filled with a clot is exposed in a septic wound. The clot then becomes impregnated with septic matter, and fresh coagulation takes place upon its proximal extremity; septic disintegration of the clot follows, and the coats of the vein become inflamed from the contact of the irritating products of the process. Thus a spreading thrombosis, followed by disintegration of the clot and inflammation of the vein, may be set up. This is a condition frequently met with in pyæmia, and is especially common in the infective inflammation of bone known as acute necrosis. In some cases of pyæmia, thrombosis, with softening of the thrombus and inflammation of the coats of the vein, is met with in parts having no connexion with the original wound. Here also it is only reasonable to suppose that the irritating properties of the thrombus are due to the presence of the infective material in the blood from which it is formed. Simple coagulation of healthy blood in a vein does not cause acute inflammation of the coats of the vessel. After the operation for varix the vein can often be clearly felt on each side of the obliterated spot as a solid cord, but none of the signs of phlebitis are present.

The most serious consequence of venous thrombosis is *Embolism*, or the separation of a clot, and its entry into the circulation. When the formation of the thrombus has been due to mechanical injury, this complication rarely takes place. Occasionally, however, after a surgical operation or parturition, a large clot may be dislodged and cause sudden death by obstructing the pulmonary artery. If the clot is not large enough to obstruct the main trunk of the artery, it may lodge in a smaller branch and recovery may follow. The following is a typical case of this kind. A man, aged 59, had been confined to bed for some weeks with a compound dislocation of the ankle; the wound was nearly healed, and he was apparently in good health. He suddenly awoke from sleep with a violent pain, which seemed to shoot up from his leg to his chest. There was immediately an intense feeling of dyspnœa, although air entered the lungs freely; the pulse rose to 120, and the action of the heart was violent and irregular. The symptoms gradually subsided, and on the third day after the attack he expectorated a small quantity of blood. Within a few hours of the attack, the symptoms of obstruction of the femoral vein manifested themselves. It was slightly tender, and could be felt as a hard cord, and great œdema of the limb appeared. Some weeks after the veins of the opposite limb became plugged in the same way, but no embolism took place.

Embolism is more commonly the result of softening and disintegration of the clot. It is possible that a healthy clot may in this way be removed without giving rise to any definite symptoms. When the softening is due to the septic changes in the thrombus, or when the clot is impregnated with the products of any infective inflammation of any kind, the virulent fragments set up inflammation wherever they lodge, giving rise to the form of

general infection known as embolic pyæmia. The pathological effects of simple and infective embolism have already been described (see Pyæmia, Vol. I., p. 981).

A softening thrombus does not necessarily give rise to embolism. In the common form of so-called idiopathic phlebitis, suppuration not unfrequently takes place round the thrombosed vein, the middle part of the thrombus is softened, the walls of the vein give way, and the *débris* of the clot are discharged with the pus of the abscess. In these cases a portion of the thrombus on each side remains unsoftened, and undergoes the ordinary changes observed in the closure of a divided vessel.

The **Symptoms** of thrombosis are merely those of obstruction of the vein. If superficial, the vein can be felt as a hard cord, with knot-like projections at the situations of the valves. If a deep vein is affected, there is cedema of the part from which it comes, often with dilatation of the superficial veins. The swollen parts are white, and pit deeply on pressure. When the coats of the vein are inflamed, the symptoms of phlebitis presently to be described will be manifest.

The **Treatment** of venous thrombosis depends entirely on the cause. When it is a part of the pyæmic process, no special treatment is of much service; when associated with phlebitis, it must be treated as described under that disease. (Edema must be treated by elevation of the limb and careful bandaging with an elastic or stocking bandage. In all cases perfect rest of the part must be maintained in order to obviate as far as possible the risk of embolism.

#### PHLEBITIS.

INFLAMMATION OF THE VEINS, originally studied by Hunter, has in later years attracted the attention of many distinguished Continental and British pathologists, amongst whom may be specially mentioned Breschet, Velpeau, Cruveilhier, Arnott, Henry Lee, Tessier, and Virchow.

**Causes.**—Phlebitis may arise from injury of the coats of the vein, from inflammation of the tissue surrounding it (periphlebitis) or from the formation of an unhealthy thrombus within it. Each of these causes may occur separately, but frequently more than one are concerned in the process. In other cases phlebitis is said to be idiopathic, which means that the cause cannot be accurately ascertained.

Traumatic phlebitis may be simple and localized, or septic and spreading. The coats of a vein, in the same way as any other tissue, become inflamed if subjected to any injury of sufficient intensity, whether it be the application of a ligature in a surgical operation, accidental mechanical violence, or the action of caustics. As the result of the injury, a clot forms within the vein, adherent to the damaged spot. If this completely occludes the vessel, it extends upwards and downwards as far as the blood in the vein is stagnant. The inflammation is however limited to the injured spot, and shows no tendency to extend. Ultimately the clot may be absorbed, and the channel of the vein restored, or the vessel may be permanently obliterated by the processes already described as occurring in arteries under similar circumstances.

Traumatic phlebitis does not however always run this simple course. When the discharges of the wound through which the vein has been injured are in

a septic condition, and the plugged vein is exposed to the direct contact of putrid matter, the thrombus may become infected. It then softens and decomposes, and thus excites inflammation in the coats of the vein, spreading beyond the part originally injured. Fresh clot, which in its turn decomposes, forms in the vein as far as the inflammation extends; and so the process may spread until some part is reached at which a large vein joins the affected trunk, when fragments of the softening clot are washed on, giving rise to the dissemination of septic emboli and pyæmia. It is this form of spreading phlebitis that was formerly so common in hospital practice. The earlier pathologists regarded the spreading inflammation of the vein as the primary cause of the mischief, whereas it is evident that it is really due to the changes taking place in the thrombus.

Spreading phlebitis may arise also without an injury in the veins leading from many infective inflammations. Either the trunk may be involved in the inflamed area or thrombosis may extend into it from the smaller veins and venules. In either case the clot becomes impregnated with the infective material, and undergoes changes of the same character as those just described.

In some cases of pyæmia or septicæmia, thrombosis may occur, as has already been pointed out, in parts distant from the seat of infection, and in these cases the clot softens and causes inflammation of the coats of the vessel. A possible explanation of this phenomenon is that the blood contains before coagulation some noxious material, which causes the subsequent softening and disintegration. In support of this theory is the fact that micrococci are found abundantly in the *débris* of the broken down clot.

Diffuse inflammation spreading from an unhealthy wound along the areolar tissue surrounding a vein may, in some cases, give rise to inflammation of its coats and thrombosis.

In addition to the above forms of the disease, phlebitis is frequently met with without our being able definitely to explain its mode of origin, and it has therefore been said to be "idiopathic." This form almost invariably affects one of the large veins of the lower extremity, usually the saphena, but occasionally the popliteal, femoral, or iliac. Most commonly the vein attacked has long suffered from varix. It seems to be most frequent when erysipelas is epidemic, but the relation between the two affections is not proved. The inflammation extends to the surrounding areolar tissue, and may occasionally end in suppuration. The clot then disintegrates, the walls of the vein give way, and the *débris* mix with the surrounding pus; but even when this happens there is but little tendency to extension of the mischief, the disintegrating clot being shut off on each side by an adherent unsoftened thrombus. When suppuration does not follow, the risk of disintegration and embolism is very slight, but it does sometimes occur and causes death.

Paget has pointed out that "idiopathic" phlebitis commonly affecting the long saphenous, but occasionally the deeper veins, is not uncommon in gouty subjects. It may occur in different parts of the same vein at the same time, and is very liable to relapses. He has termed the affection "gouty phlebitis," and believes that it commences as a gouty inflammation of the coats of the vein.

**Pathological Anatomy.**—The coats of an inflamed vein are swollen and rigid, and of a redder tint than natural from injection of the vessels of the

outer coat. The surrounding tissues are usually cedematous. In septic or infective phlebitis the walls of the vein are softened, and often give way opposite the disintegrating portions of the clot; and wherever this happens a collection of pus forms outside the vessel. The conditions of the thrombi in inflamed veins have already been sufficiently described (see Venous Thrombosis). Microscopic examination shows the coats of the vein to be infiltrated with small round cells; the endothelium is at first swollen, and if softening of the thrombus takes place, is lost in the disintegrating clot.

**Symptoms.**—In idiopathic or gouty phlebitis of a superficial vein the symptoms are very evident. The patient has usually suffered from varicose veins before the attack. The inflammation is localized, usually affecting a few inches of the vessel, and sometimes two or more parts at the same time. The vein becomes hard, swollen, knobbed, and painful, the knobs constituting distinct enlargements opposite the valves, or in the pouch-like dilatations of the varicose vein. The skin covering it assumes a reddish purple colour, and there may be stiffness, or inability to move the limb. There may perhaps be no pain when the limb is at rest, but in some cases severe shocks of pain, resembling neuralgia, dart along the line of the vein. In all cases there is acute tenderness over the course of the vessel. There is always some œdema around the inflamed vein, but if a single superficial vein is affected there is but little swelling of the parts that supply it with blood, owing to its free communications with the deep veins.

When the deep veins are affected the most marked signs are deep-seated acute pain and tenderness, with marked œdema of the parts from which the vein derives its blood. This cedematous condition of the limb is a most important diagnostic sign of deep-seated phlebitis when the vein cannot be felt (as in the pelvis for instance), and may be the first symptom observed, coming on either suddenly or gradually. The œdema may give rise to a hard, white, tense condition of the limb, which pits on pressure, though in some cases the hardness is too great for this, as is seen in the ordinary "white leg" following parturition. Occasionally in deep phlebitis the limb may suddenly swell to a considerable size without there being any subcutaneous œdema. In phlebitis of the deep veins of the leg and thigh, the calf of the affected limb may suddenly enlarge, with great pain and much distension of the superficial veins with fluid blood, but without any subcutaneous œdema. As the inflammation subsides the pain and tenderness disappear; and if superficial, the distended vein, with its solid contents, becomes more clearly defined. In varicose veins complete obliteration of the vessel may take place, the hard cord gradually diminishing in size till it is no longer perceptible. If the deep-seated veins are affected the œdema continues long after the signs of inflammation have disappeared, perhaps for many months, till either the channel of the vein has been restored or the superficial veins have enlarged sufficiently to carry back the blood without difficulty. If suppuration takes place in phlebitis of a superficial vein, the symptoms are those of an ordinary acute abscess. When the deep veins are affected, the symptoms are less clear until the accumulation becomes of sufficient size to give a distinct sense of fluctuation. In these cases there is but little fear of pyæmia, as the vein is closed by a firm adherent clot on each side of the part in which suppuration is taking place. After the resulting abscess has been opened, however, spreading septic phlebitis, followed by pyæmia, may occur unless

proper antiseptic precautions are taken to prevent it. The constitutional disturbance in this form of phlebitis is not severe unless suppuration takes place, and even then it speedily subsides as soon as the pus is evacuated.

The symptoms of *spreading septic phlebitis* of the deep veins are less evident, being concealed more or less completely at first by the unhealthy inflammation taking place in the part from which the mischief has started, and later on by the grave constitutional symptoms of pyæmia which speedily manifest themselves. Pain and tenderness in the line of the vein, with considerable œdema rapidly coming on, would lead to a suspicion of its occurrence. The superficial veins are less commonly affected, but should they be implicated, the symptoms are those of superficial phlebitis just described, differing only in the steady extension of the redness and pain up the course of the vein, and in the presence of the general symptoms of blood-poisoning.

**Treatment.**—The first point to be attended to in the treatment of phlebitis is absolute rest of the limb in an elevated position. The importance of rest in these cases is twofold: first, to prevent pain and increase of the local mischief; and secondly, to guard against the danger that may result from the detachment of the thrombus, which, carried into the circulation, may occasion sudden death by plugging of the pulmonary artery, or more remotely, in cases of septic phlebitis, by pyæmia. Should the affected veins be situated in the neighbourhood of a joint, the limb may be kept at rest by means of a well-padded splint.

In simple or gouty phlebitis, much local comfort is derived from the application of Extract of Belladonna and Glycerine, in equal parts, covered by a hot fomentation and a thick layer of cotton-wool loosely secured by a bandage. Should this application not be at hand, simple hot fomentations will afford great relief. The constitutional treatment must be conducted on ordinary medical principles in accordance with the age and strength of the patient, depletory measures always being avoided, and early recourse being had to a tonic or stimulating plan. The hardness that is often left after the subsidence of the inflammation will gradually disappear without any special treatment. If œdema of the limb continue, the pressure of an elastic roller will remove it. But if the œdema has been extensive and chronic the limb rarely, if ever, completely recovers its natural size.

If abscesses form they must be treated by free and early incisions, the most scrupulous attention being paid to the prevention of decomposition.

In spreading septic phlebitis treatment is of little avail. If a superficial vein is affected it would be justifiable to expose the vein above the affected part and remove a portion of it to arrest the progress of the disease. If the deep veins are affected and the diagnosis can be clearly established, and especially if rigors and other symptoms of blood-poisoning are present, amputation may give the patient a last chance. This form of phlebitis is, however, almost certainly preventable by any efficient antiseptic mode of treating wounds.

In those cases in which a similar condition is set up in the vein leading from an area of infective inflammation, not septic in character, as in acute necrosis of bone, the diagnosis is almost impossible until it is too late for amputation to be of any service.

## VARICOSE VEINS OR VARIX.

By VARICOSE VEINS or VARIX is meant a permanent dilatation of the veins with thickening of their walls. Varix must be distinguished from simple dilatation or phlebectasis such as arises from acute obstruction to the return of blood, or from the pressure of a tumour or aneurism. Simple dilatation subsides as soon as the cause is removed, and it is not accompanied by any definite change in the structure of the walls of the veins; varix is permanent and is always associated with degenerative changes in the coats of the affected vessel.

**Causes.**—The causes of varix are generally *such conditions as induce more or less permanent or frequently repeated distension of the veins*. Thus, for instance, strains and habitual over-exertion of a limb, by driving the blood from the deep into the subcutaneous veins, may give rise to distension of them; so also sedentary occupations and prolonged standing tend to favour accumulation of blood in the veins of the lower extremities. Any obstacle to the return of blood from a vein (as the pressure of a tight garter below the knee, or of a tumour upon one of the large venous trunks), may give rise to permanent distension if it act for a sufficient length of time. When the vein has become sufficiently dilated to render its valves incompetent, the tension of the walls of the veins is greatly increased by the weight of the unbroken column of blood, and the condition thus becomes aggravated. In all cases in which the tissues are congested from any obstruction to the return of blood, the walls of the veins suffer with the other parts, and are thus rendered more prone to degenerative changes.

In some cases the affection, or the disposition to it, appears to be *hereditary*; and in many instances it is difficult to recognize any cause except an *enfeebled and relaxed state of the walls of the vessel*, such as is met with in tall, debilitated, and phlegmatic people. Age materially influences the occurrence of the disease, which, rare in the earlier periods of life, gradually increases in frequency up to middle age when the tendency ceases. In *women*, especially, the affection is common—in consequence, partly, of natural debility, but more frequently from the pressure of the enlarged uterus during pregnancy.

**Locality.**—The veins of the skin and the mucous membranes are those that are most liable to varix. It is most commonly met with in the legs, and more particularly in the trunk of the internal saphena. Simple dilatation may be met with in any of the superficial veins, as of the chest, arms, head, neck, hypogastrium, or thorax, but true varix in these situations is rare. The veins of the anus and lower part of the rectum are especially liable to varix, as they are but loosely supported by the surrounding parts, and are subject to over-distension from any cause that obstructs the hepatic circulation, such as cirrhosis of the liver. The spermatic veins also often become enlarged, constituting varicocele.

True varix is infinitely more common in the lower than in the upper part of the body, owing evidently to the influence of gravity in causing tension in the more dependent vessels. Dilatation of the veins at any point above the pelvis arises in most cases from the pressure of a tumour of some kind upon the large venous trunks, the superficial veins being enlarged to take the place of the deeper vessels that are obstructed. This condition may end in true varix, but if the enlargement is sufficient to enable the vein to carry the required quantity

of blood easily there will be none of those changes of the coats which constitute true varix and are the result of abnormal tension. The deep-seated veins that are principally affected are the internal jugulars, the vena azygos, and the veins of the prostate.

**Morbid Anatomy.**—Veins that are simply dilated (phlebectasis) differ from true varicose veins in being merely increased in size, without any alteration in structure. Their walls are thin and soft, and they collapse readily. A varicose vein is increased in diameter and elongated, forming curves and bending back on itself. Sometimes the enlargements at particular points appear multilocular, the vein forming a series of curves and dilatations lying closely packed together. The coats of the vein are opaque, and thickened often to such an extent that the divided vessel stands open like an artery. Occasionally calcareous plates are met with in the thickened walls. On opening the vein the valves are always found to be insufficient; sometimes they have disappeared altogether, and in other cases they form small ridges or bands projecting from the wall. When the vein has been cut up it will be seen that in some of the pouch-like dilatations the wall has become greatly thinned. The inner coat of the vein appears smooth and but little altered, beyond being often marked by longitudinal striae. When the vein is subcutaneous, the small branches entering the trunk from the skin are often dilated, and this condition may sometimes be traced here and there into the cutis, which is thinned over the dilated vessel. In the wall of the vein and in its sheath small dilated veins belonging to the vasa vasorum are very commonly observed.

Microscopic examination shows that the thickening of the vein is chiefly due to a development of dense fibroid tissue in the middle coat. The muscular fibre cells are somewhat increased in number, but are separated widely from each other by the fibroid tissue. The outer coat is also thickened; the inner shows but little change. In the thinned pouches, the middle coat is atrophied, and may have completely disappeared.

**Appearances and Symptoms.**—Varicose veins are tortuous, dilated, and sacculated; they are serpentine in their course, and feel thick under the finger. When superficial, the disease is often limited to one of the larger venous trunks, the smaller branches not being implicated. This we commonly see in the internal saphena. The pouch-like dilatations may often approach very closely to the surface, the skin being thinned over them, and the blue tint of the vein being readily perceptible. When the patient is erect the veins become more prominent and tense. In other cases the small superficial veins are affected, appearing in the skin as a close network of a purplish-blue colour, causing much discoloration of the parts. Both sets of vessels may be implicated. In consequence of the incompetence of the valves an impulse can often be felt even below the knee when the patient is made to cough. Varix of the deep veins is less common, as the vessels are better supported by the surrounding parts. They give rise to no appearance which can be recognized during life. Varicose veins cause a sense of tension and weight, often with considerable smarting or pricking pain in the parts from which they return the blood. Sometimes they may cause numbness, difficulty of movement, or even some loss of power in the affected limb. These symptoms are aggravated by exertion, and in deep-seated varix they are often very marked.

**Progress and Effects.**—Varicose veins never undergo spontaneous cure;

when once formed, the condition is permanent, unless the vessel become plugged by coagulum, when it may be obliterated. The current of blood is then diverted into other channels, and as a rule these in their turn become varicose. The main evil that results from varicose veins in the legs is the change that is slowly induced in the nutrition of the skin and subcutaneous areolar tissue, by the retardation of the circulation, and the interference with the due return of blood. The parts from which the vein derives its blood are often slightly cedematous. After a time the subcutaneous fat becomes indurated, and the skin loses its elasticity, becoming rigid and often darkly pigmented in places. In consequence of the imperfect nutrition of the parts ulceration frequently takes place, especially below the middle of the leg. The ulcer has a great tendency to assume the chronic or callous form. Chronic eczema is a frequent consequence of the congestion of the skin caused by varicose veins. There is another accident that may occur as the result of varicose veins of the legs, viz., that the varix may give way—the vein may “burst” as is generally said. In these cases, the word “burst” is scarcely correct. The varix does not give way solely by pressure from within; but a process of ulceration goes on from without by which its coats become weakened, so that at last a pin-hole aperture forms, giving rise to profuse hæmorrhage. The bleeding is often so abundant as to induce faintness, and sometimes even death in a few minutes. It takes place in a different way from ordinary venous hæmorrhage, the blood coming chiefly from the cardiac and not from the distal side, the incompetent valves not presenting the ordinary obstacle to the downward flow of blood. It is this that causes its extraordinary copiousness. In most cases this so-called “bursting” is not so sudden but that a Surgeon may foresee the probability of its occurrence, as it most commonly takes place either on the surface of an ulcer, or is preceded by induration, reddening, and thinning of the integuments covering the diseased vein. In some cases, however, the warnings may be very slight. A few years ago a man was brought into University College Hospital, who had died in a few minutes from hæmorrhage from a varicose vein. There was nothing to be seen on the body but a minute hole, surrounded by apparently healthy skin. Water injected into the vena cava readily flowed out through the aperture. On injecting the specimen and dissecting it, a large mass of tortuous veins was found (Fig. 426), but the hæmorrhage had come from a small cutaneous vein which joined the varicose trunk. It had been dilated to the size of a crow-quill, and the cutis covering it was thinned. Varicose veins are very prone to suffer from inflammation and thrombosis. The symptoms are those of phlebitis already described. The inflammation is usually localized. Suppuration occasionally takes place, but spreading phlebitis and embolism are rare complications. After an attack of phlebitis the vein is often obliterated, and the patient cured of his disease.

Fig. 426.—Varicose internal saphenous vein with a piece of skin attached. *a*. A small cutaneous vein dilated from which fatal hæmorrhage occurred.

**Treatment.**—This must be conducted on two principles—to palliate and to cure. The **Palliative Treatment** consists in moderate compression exercised upon the vessel, so as to support its weakened and dilated coats, and thus prevent its further distension and the pain occasioned by this, as well as the other consequences—such as œdema, induration and ulceration. The pressure must be applied very smoothly and evenly, lest it irritate the skin and cause ulceration, or produce distension of the vein below the part compressed. For the purpose of compression, bandages and elastic stockings are commonly employed. The soft “stocking bandage” is one of the most comfortable. If an elastic stocking be used, care must be taken that it really fits evenly. They are often made too tight at the upper part. Martin’s india-rubber bandage applied in the same way as in the treatment of the chronic ulcer (Vol. I., p. 280) is a most efficient and comfortable mode of treatment if the patient can wear it without its causing eczema. Elastic pressure by means of an india-rubber band around the limb, and the application of a tross to the upper part of the saphena vein as advised by Colles, are modes of treatment which aggravate rather than relieve the symptoms.

If a vein burst, the hæmorrhage is easily arrested by placing the patient on his back with the leg elevated and applying a compress and bandage. When a patient is in danger of hæmorrhage, he should be advised to have the vein at once obliterated; and if this cannot be done, it should be explained to him that if bleeding comes on he has nothing to fear, if he lies on his back and elevates his leg against some convenient object nearly to a right angle with his body, till assistance can be obtained. The application of a finger to the bleeding spot would immediately arrest the hæmorrhage. When death takes place, it is while the patient is foolishly running about to seek assistance.

In certain circumstances, it becomes necessary to change the palliative for a **Curative** plan. This is especially requisite if the varix be so large as to cause much inconvenience, or to give rise to severe pain by its pressure on the nerves in its neighbourhood; or if a varicose vein have burst, or be on the point of giving way.

Whatever method of curative treatment is adopted a simple traumatic inflammation of the vein is caused, and, as the result of this, thrombosis occurs in the vein as far as the next branch on each side of the part obliterated. Finally, the thrombus is gradually replaced by connective tissue and thus the vein is reduced to a solid fibrous cord. If septic inflammation occurs in the wound around the vein there is considerable risk that the localized traumatic phlebitis may be converted into a spreading septic form. Softening of the clot is then a likely danger and may lead to pyæmia.

By these means the trunk of a varicose vein and the larger masses of varix may be occluded. But can the disease be cured by the local obliteration of the vein? This question I have no hesitation in answering in the negative. Though the trunk be obliterated, a collateral venous circulation is set up, which is very apt in the course of a few months to take on a varicose condition, and thus to cause a return of the disease. But, though the cure be not radical, much benefit may often be effected by removing varicose knots that occasion pain or inconvenience, or by occluding a vein from which hæmorrhage has occurred or is threatening to occur.

Various plans for obliterating the veins have been recommended, but by

far the most efficient is the *excision of a portion of the vein* between two ligatures. This operation may safely be undertaken if any efficient mode of antiseptic treatment be adopted. Without this it is not unattended with danger from septic changes in the thrombus followed by pyæmia. Before the operation the position of the affected veins should be marked on the limb with an aniline pencil, whilst the patient is standing. This is far better than the application of a bandage round the upper part of the limb during the operation, as it is inconvenient to operate when the veins are distended. The limb must then be wrapped for at least half an hour in a towel soaked in carbolic lotion (1 in 20), and finally sponged with a solution of perchloride of mercury (1 in 500). The varicose vessel is then exposed by a small longitudinal incision about an inch in length. The vein is next separated from the surrounding tissues, seized in two pairs of force-pressure forceps and divided. Each end of the vein is then drawn firmly out of the wound and ligatured with fine silk or chromicized catgut. Finally, the two portions of the vessel are cut off close to the ligatures, any small tributaries entering them having previously been tied.

The operation is repeated in as many places as may seem to be necessary to ensure the complete occlusion of the diseased vein. The edges of each wound may be brought together by horse-hair sutures, after which an absorbent antiseptic wool dressing may be applied and left untouched for a week, at the end of which time the small wounds will usually be healed.

In some cases in which the main trunk of a vein, especially the internal saphenous, is chiefly affected, it may be thought advisable to excise the vessel more widely through a long incision over it. It is doubtful, however, whether this gives a better result than the removal of two or three short pieces in the manner above described.

It not uncommonly happens that varicose veins of the lower extremity which seem suitable for operation are associated with the presence of an ulcer in the lower third of the leg, and the question arises whether this complication is a further indication or not for undertaking the operation. Undoubtedly the obliteration of the diseased veins favours the cicatrization of the ulcer, but it is equally certain that with efficient dressing in the recumbent position such ulcers very rarely fail to heal. As, therefore, the presence of the ulcer must add to the risk of septic contamination of the operation wounds, it is probably wise as a rule to defer the operation until the ulcer has healed. The obliteration of the veins will then probably render the healing permanent. If however the operation be undertaken whilst the ulcer is still unhealed, the latter should first be thoroughly cleaned and dressed antiseptically, and the dressing may be left undisturbed until the wounds have united.

Before the introduction of the antiseptic treatment of wounds various subcutaneous methods were employed for the obliteration of varicose veins :—

1. A simple but uncertain method consisted in the division of the vein by a subcutaneous incision, followed by the application of a compress and bandage.

2. At one time the treatment almost universally employed consisted in compressing the vessel at several points by passing a hare-lip pin underneath a laying a piece of wax bougie over it, and then applying a figure-of-8 suture around the pin and over the bougie. By this means obliteration of the vein was produced by the pressure exercised upon it, and the presence of the bougie prevented the ligature from injuring the skin. The pins were removed

at the end of a week or ten days. This method gave excellent results, and the chief danger consisted in the possible transfixion of the vein by the pin, followed by septic changes in the thrombus.

3. Injection of the varix with a few drops of a solution of perchloride of iron, as recommended by Pravaz, was performed with the object of producing coagulation of the contained blood and consolidation of the varix. The vein was compressed by a tourniquet applied above the varix for at least half an hour after the operation, for fear of embolism. Local suppuration and sloughing, pyæmia, and even fatal embolism, have occasionally followed this mode of treatment. Of these older methods the compression of the veins by pins was undoubtedly the safest and most efficient, but at the present day all other methods have been largely superseded by antiseptic ligature and excision.

## CHAPTER XLI.

ANEURISM BY ANASTOMOSIS, AND NÆVUS.—  
HÆMORRHAGIC DIATHESIS.

## ANEURISM BY ANASTOMOSIS.

**Aneurism by Anastomosis**, or **Cirroid Aneurism**, is a rare disease of the arteries, in which they become excessively elongated, tortuous, and serpentine; sometimes they assume a varicose condition, being dilated into small sinuses, and they are always very thin-walled, resembling veins rather than arteries in structure. This kind of dilatation of the vessels gives rise to pulsating tumours, often of considerable size, and of a very active and dangerous character. They may be situated in almost any tissue or organ of the body, but are generally met with in the submucous and subcutaneous areolar tissue, and most frequently in the upper part of the body, especially about the scalp, orbit, lips, and face; but they have been seen in other situations, such as the tongue, and even in internal organs, as the liver; and I have had under my care tumours of this kind on the side of the chest, nates, and foot. It will generally be found that the arteries leading to an aneurism by anastomosis, though at a considerable distance from it, are tortuous and enlarged, with thin and expanded coats, and pulsate actively; in fact, constituting that condition that goes by the name of **Cirroid Dilatation** of the vessels.

Aneurisms by anastomosis form tumours of varying size and irregular shape; they are usually of a bluish colour, have a spongy feel, are readily compressible, not circumscribed, and have large tortuous vessels running into and from them on different sides. Their temperature is generally higher than that of neighbouring parts; and a vibratory or purring thrill, with distinct pulsation, may be felt in them. This is synchronous with the heart's beat, may be more or less completely arrested by compressing the tumour or the arteries leading to it, and returns with an expansive beat on the removal of the pressure. The bruit is often loud and harsh, but at other times of a soft and blowing character. These tumours rarely occur in infancy, but generally make their appearance in young adults, though they may be met with at all periods of life, often as the consequence of injury.

**Diagnosis.**—It is of importance to make the diagnosis between *ordinary aneurism* and that by anastomosis. In many cases the situation of the tumour at a distance from any large trunk, as on the scalp, the outside of the thigh, or the gluteal region, will determine this. Again, the outline of the tumour is less distinct than in true aneurism; and tortuous vessels will be felt leading to it from different directions. The swelling also is doughy and very compressible; but, when the pressure is removed, the blood enters it with a whiz and thrill, not with the distinct pulsating stroke that is found in aneurism.

The pulsation, not so forcible as in aneurism, is more heaving and expansile. The bruit is louder, and more superficial, sometimes having a cooing tone. By pressure on the arteries leading to the tumour these signs are usually not entirely arrested, though diminished in force, the blood entering it from the neighbouring parts, and in a less direct way.

**Treatment.**—The treatment of aneurism by anastomosis must depend upon the size and situation of the growth. When it is so placed that it can be *ligatured* or *excised*, as on the lip, or when small, about the neck, face, or scalp, trunk or extremities, it should be removed. I always prefer the ligature, applied as will immediately be described, as being the safest, and upon the whole the readiest mode of removing such a tumour. If excision be practised, it is necessary to be very careful to cut wide of the disease; if it be cut into, fearful hæmorrhage may ensue, which can only be arrested by pressure, and which in several instances has proved fatal.

If the disease be very large and extended, as is commonly seen on the scalp, or if deeply seated, as in the orbit, neither ligature nor excision of the tumour can be practised, and it becomes necessary to starve it by cutting off its supply of blood. This may be done either by *ligaturing the principal branches leading to it*, or *the main trunk* of the limb or part.

Simple ligature of the *arterial branches leading to the tumour* has never, I believe, been followed by success; at least, in ten recorded instances in which it has been had recourse to, the disease has not in one instance been cured. It has, however, been successfully conjoined by Gibson, in two cases of aneurism by anastomosis of the scalp, with incisions made round the tumour at intervals between the principal feeding arteries, which at the same time were tied.

The *main trunk leading to the tumour* has been ligatured in a considerable number of cases. The brachial and femoral arteries have been tied for disease of this kind situated on the extremities, and in some instances with success; but the carotid is the vessel that has been most frequently deligated, in consequence of the tumour being commonly situated on the scalp and in the orbit. Wyeth has collected 98 cases in which the carotid was ligatured for vascular growths above the clavicle, excluding cases of "intra-orbital aneurism." The results have not been encouraging: of 73 cases in which the common carotid was tied, nearly 30 per cent. died directly from the operation, and only about half of those that recovered derived any benefit from it. Both common carotid arteries were tied at varying intervals in 9 cases; of these 2 died, 1 was cured, 2 improved, and the rest recovered but derived no benefit from the operation.

In many of the cases in which one carotid alone was tied, the disease, being seated upon the scalp, was not cured; and it was afterwards found necessary to have recourse to ligature of the tumour, to excision, and to other means of removal; indeed, when seated upon the scalp, this disease appears to be more intractable than in any other part of the body, owing probably to the freedom of the arterial supply from the numerous vessels that ramify in this region. Here, however, much benefit might be derived after ligature of the carotid, by adopting the plan, suggested by Gibson, of tying the feeding arteries, and making incisions between them down to the bone. The ligature of the carotid has answered better for pulsating tumours in the orbit, but few of these are true cirroid aneurisms. (See Intra-Orbital Aneurisms.)

## NÆVUS.

This disease, under which are included those various affections termed **Mother's Marks, Erectile Tumours, and Vascular Growths**, constitutes an important and interesting section of surgical affections.

Nævi are usually divided according to their structure into two chief varieties: *capillary* and *venous* or *cavernous*. Aneurism by anastomosis was formerly included under the name of arterial nævus. The simple capillary nævi are composed merely of the capillary vessels of the skin greatly increased in size and number; the cause of their growth is quite unknown. Venous or cavernous nævi are usually definitely circumscribed tumours, composed of spaces lined with an endothelium similar to that of the veins and bounded by a thin wall. The whole mass is bound together by a delicate areolar tissue. The spaces are filled with dark venous blood. The arterial supply is usually small, and the arteries open directly into the spaces, without the intervention of capillaries. In some cases, however, a venous nævus is not clearly defined, but consists of a mass of tortuous, thin-walled veins, surrounded by a considerable quantity of areolar tissue, sometimes containing fat. In fact, the structure of nævoid growths varies considerably in different cases, and the various forms merge into each other. (See also Angiomata, Vol. I., p. 1028.)

Superficial nævi are divided into the *cutaneous* and *subcutaneous* varieties. The former are capillary in structure; whilst the subcutaneous nævi, although usually venous, are also occasionally found to be entirely composed of a mass of capillary vessels. The most common condition is to find the two forms of nævus conjoined, the disease assuming the capillary form in the skin and the venous beneath.

According to R. W. Parker, 67 per cent. of nævi occur in female children. They are almost always, if not invariably, congenital. Cavernous nævi occasionally appear in adult life, but it is probable that these are of congenital origin, and commence active growth at an unusually late period.

**Capillary Nævi** appear as slightly elevated but flat spots on the skin, of a bright red or purplish tint, and having occasionally granular or papillated elevations, with some larger vessels ramifying on their surface. They often spread superficially to a considerable extent; they are usually situated on the face, head, neck, or arms, but occasionally, though more rarely, on the back, the nates, the organs of generation, and the lower extremities. They are often at birth very small, not larger than a pin's head, from which they may spread in the course of a few weeks or months to patches an inch or two in diameter. In many cases no inconvenience results from this disease, except the deformity it causes; but occasionally, more especially when the growth is at all prominent, there is a great disposition to unhealthy ulceration. When bleeding occurs from a wound of the nævoid structure it is usually in a trickling stream, and without any degree of force.

**Venous or Cavernous Nævi** are of a dark purple or reddish colour, usually very prominent, and often forming distinct tumours of considerable size, which may either be smooth and ovoid, or somewhat lobulated. On compressing a growth of this kind, it subsides to a certain extent, feeling doughy, soft, and inelastic; on the removal of the pressure it fills again. In some cases, when consolidated by inflammation, or containing cysts, they cannot be lessened in bulk by pressure. These nævi are usually of about the size of half

a walnut, but sometimes much larger. I have removed from the nates and the back some quite as large as an orange. They occur less frequently upon the head and face than the capillary form of the disease; most of the instances that I have seen have been in the lower part of the body, about the nates, back, lower extremities, and organs of generation.

When a venous *nævus* is purely subcutaneous, it forms a soft, doughy tumour, often clearly defined in outline. Its most characteristic feature is that it can be diminished by pressure, on the removal of which it slowly fills out again to as large a size as before; it also becomes distended when the child screams or struggles. It is usually oval, smooth, and uniform in outline. Occasionally the surrounding veins are bluish and enlarged.

In rare instances a *nævus* may be deeply situated, and thus give rise to a tumour, the nature of which may be very obscure. The difficulty in diagnosis is obviously greater if the tumour is noticed for the first time in adult life. In University College Museum a cavernous *nævus* is preserved which was removed by Christopher Heath from the temporal fossa of a man aged forty-five. The tumour had been noticed for fifteen years. It had recently taken on rapid growth, and before removal was thought to be sarcomatous. These deeply-seated *nævi* may sometimes invade, or apparently originate in, the substance of a muscle.

Cysts are sometimes found in *nævi* containing a dark fluid. They result from obliteration of the communication between some of the spaces of the *nævus* and the vessels which carry off the blood. The tumours once supposed to be consolidated *nævi*, with cysts scattered through them containing clear fluid, are now regarded as of lymphatic origin.

**Prognosis.**—The natural history of *nævi* is somewhat uncertain. They are so commonly removed by operation, that we have yet to ascertain what becomes of them when left to themselves. I have, however, seen several cases in which from various circumstances no operation had been performed, and I have been struck by the tendency that there is in the cutaneous *nævus* to disappear. If left untouched, or subjected to continuous pressure, islands or patches of white skin will gradually appear on the reddened surface. These will slowly increase and coalesce, and then the *nævus*, becoming gradually less vascular, may in time disappear. Subcutaneous venous *nævi* will sometimes gradually shrink, but the active erectile *nævus* is always progressive.

There is usually a fear expressed of *nævi*, if left without surgical interference, leading to dangerous or even fatal hæmorrhage. This I have never seen; indeed, if the *nævus* ulcerates its tissue hardens, and the vessels become blocked up by coagulum and hence less disposed to bleed.

**Treatment.**—In the treatment of *nævus*, the first point to be determined is whether the case should be left to nature, or whether operative measures should be had recourse to. In deciding this we must be guided by the size, situation, and character of the morbid growth. If it be small, cutaneous, and superficial, so situated that it occasions little or no disfigurement, and if it show no tendency to increase, it may be left without interference; when, as just stated, it may eventually shrivel and disappear, or become converted into a kind of mole. In some cases this process may be hastened by the application of tincture of iodine or liquor plumbi. In other cases, again, the *nævus*, though cutaneous and superficial, is so widely diffused over the surface, that no attempt at its removal or destruction can be entertained with prudence.

But, if the nævus be large, if it be subcutaneous, if it increase in size, or if it be so situated as to occasion disfigurement, means must be adopted for its removal by operative procedure.

*Operations* for the removal of nævi may be conducted on six principles :— 1, to excite inflammation in them, and so to produce plugging and obliteration of the vascular tissue of which they are composed ; 2, to destroy the growth by caustics ; 3, to remove it by the cautery ; 4, to consolidate it by electrolysis ; 5, to remove it with the knife ; or, 6, to remove it by ligature. Each of these different plans of treatment is applicable when the disease assumes certain forms, and affects certain situations. It will be convenient to consider separately the treatment of the cutaneous, and the subcutaneous or mixed, varieties.

**Cutaneous Nævus.**—A very minute cutaneous nævus can sometimes be obliterated by painting it repeatedly with contractile collodion. *Vaccination* has been extensively practised, but a nævus suitable for this treatment can be much more conveniently destroyed by other methods. A cutaneous nævus of moderate size in such a position that the presence of a linear scar is unimportant, is best treated by *excision*. An elliptical incision is made around the growth, and the edges of the wound are accurately brought together with horse-hair sutures. If excision is not practicable the nævus may be destroyed by the use of the *cautery* or by *caustics*. Paquelin's cautery is very convenient for this purpose ; the fine point may be drawn in lines across the surface of the growth, or numerous punctures may be made into it, especially around the margin. After the operation boric acid ointment or some other simple dressing must be applied. Care must be taken in applying the cautery to large nævi not to use it too freely, otherwise troublesome ulceration may be caused by the sloughing of the skin. The galvanic cautery may be used in the same way.

Caustics may very conveniently be used when the nævus is small, very superficial, of the capillary character, with an exceedingly thin covering of cuticle, and so situated, as upon the arm, neck, or back, that a moderate amount of scarring is of little consequence. Nitric acid is perhaps the most useful. It should be well rubbed on by means of a piece of stick. The skin round the nævus may be greased to prevent its being accidentally touched by the acid ; and as soon as the caustic has been sufficiently rubbed in, it must be neutralized with some carbonate of soda. After the separation of the slough, the application must be repeated as often as there is any appearance of prominent granulations springing up, which occasionally happens at one angle of the wound, and indicates a recurrence of the vascular growth.

Acid nitrate of mercury and ethylate of sodium may also be used for destroying small cutaneous nævi. The ethylate of sodium, which was introduced by B. W. Richardson, is employed in the form of the official alcoholic solution. It is applied with a small glass rod, and causes the separation of a very superficial slough which leaves little scarring.

The treatment of extensive "port-wine stains" on the face is very unsatisfactory. Linear scarification has been recommended by Balmano Squire with the object of causing obliteration of the dilated capillaries, and electrolysis has been tried for the same purpose, but neither method seems to be of much service.

**Subcutaneous and Mixed Nævi.**—*Excision* when practicable is the best

treatment for these varieties of *naevus*. It may, however, be rendered impossible by the large size of the growth, or by its position, as for instance in the neighbourhood of the orbit, whilst the resulting scar is an objection to the excision of most *navi* situated on the face. The most favourable cases for this treatment are those in which the tumour is distinctly circumscribed. It can then be dissected out with but little risk of hæmorrhage by keeping carefully outside the capsule, for, as Pridgin Teale has pointed out, the feeding arteries are few and small. Should the *naevus*, however, be diffused without any distinct limiting capsule, care should be taken to cut wide of the disease; and in such cases, as a rule, it is safer not to attempt the operation unless the growth is so situated that hæmorrhage may, if necessary, be readily controlled by pressure after the operation. Excision is the only suitable treatment for a *naevus* which has become cystic or lipomatous.

In cases in which there is likely to be much hæmorrhage, the method of excision recommended by Davies-Colley will be found very useful. Two long hare-lip pins or straight needles are passed at right angles to each other under the *naevus*, and beneath the projecting ends a piece of fine elastic tubing is tightly passed so as to surround completely the part in which the incisions are made. Finally two or more wire sutures are introduced beneath the *naevus*. The latter is then excised and no bleeding occurs until the pins are removed, when it can be arrested by tightening the deep silver-wire sutures.

*Electrolysis*, or *galvano-puncture*, is best adapted to those cases of deep-seated *navi* in which from their position excision is impracticable, or to those so situated as to make it important to leave as little scarring as possible. The operation is performed by passing into the *naevus* two needles, insulated except for the last quarter of an inch by a coating of copal varnish or vulcanite, and then connecting them with a galvanic current from one of the ordinary medical batteries. The current should be strong enough to decompose water, and it may be gradually increased and the effect watched. The tumour becomes hard somewhat suddenly, and assumes a pale or almost white tint; this is a sign that enough has been done. The moment the earliest sign of hardening appears the needles should be disconnected, and connected with the opposite poles of the battery, so that the needle which was negative becomes positive. By doing this, hæmorrhage is prevented when the needles are withdrawn, as the salts of iron formed by solution of the positive needle serve as an efficient hæmostatic. If gas bubbles out alongside the needles it is a sign that the current is too strong, and some cells should be taken off, or sloughing may result. In deep-seated *navi* the effect can be judged of only by the hardening of the tumour. The operation has often to be repeated several times before the *navus* is finally cured.

If the somewhat tedious process of the cure by electrolysis is considered a serious drawback, and in cases in which it has been unsuccessfully tried, the *cautery* may be used. The heated platinum wire of a *galvano-cautery* or the fine point in Paquelin's apparatus is passed freely in different directions into the substance of the *naevus* through one or more punctures in the skin. Care must be taken not to make too many punctures, lest the whole mass slough. In this way a large *naevus* can often be destroyed with comparatively little loss of skin, a smooth white scar being left. It is often necessary to repeat the operation before the cure is complete. Another useful plan is to break up the substance of the growth subcutaneously by means of a cataract needle, or

tenotome, and in the intervals between the different introductions of this instrument to keep up pressure upon the tumour.

The two remaining methods which have been extensively used in the treatment of subcutaneous nævus are the ligature and injection. At the present day, however, both these methods have to a large extent fallen into disuse, as cases are rarely met with which cannot be treated by the simpler and safer methods above described.

*Injection* of a nævus with some fluid capable of causing coagulation of the contained blood is attended with the danger of sloughing, and of extension of the coagulation into the vessels beyond the nævus with resulting dangerous or even fatal embolism. In order to prevent this latter accident, a tourniquet should be placed on a limb if it be the seat of the nævus. If the nævus is seated on any other part, two hare-lip pins must be passed beneath it, and a temporary ligature applied beneath the pins during the operation; this can safely be removed after about a quarter of an hour.

The solution of perchloride of iron has been most generally used, and should be injected into the substance of the nævus by means of a small glass syringe with a screw-piston rod and a fine sharp pointed platinum nozzle (Fig. 427). In doing this, care must be taken that but a very small quantity of the solution, not more than two or three drops, be injected at one time: if more than this be used, the tissue of the nævus may have its vitality destroyed, and slough. If preferred, a few drops of a strong solution of chloride of zinc, or pure carbolic acid, may be injected instead of the perchloride of iron.

The *ligature* requires to be applied in different ways, according to the size and situation of the tumour. In all cases, the best material is firm, round, compressed whip-cord, which has previously been rendered aseptic by carbolic acid or perchloride of mercury. This should be tied as tightly as possible, and knotted securely, so that no part of the tumour may escape complete strangulation. It is well, if possible, not to include in the noose any healthy skin, but to snip across with a pair of scissors that portion of integument which intervenes between the cords that are tied together; at the same time, care must be taken to pass the ligatures well beyond the limits of the disease. After the growth has been strangulated it may be punctured to let out the blood, and then injected with a few drops of chloride of zinc (1 in 40) or carbolic acid. Its surface may then be dusted with iodoform, and covered with iodoform wool, sealed down with collodion. The mass thus forms a dry aseptic scab, which separates in a few days, with scarcely any suppuration, leaving a healthy sore beneath.

When the tumour is small, an ordinary double ligature may be passed across its base, by means of a common suture-needle; and, the noose being cut and the thread tied on each side, strangulation will be effected. When it is of larger size, and of round shape, the most convenient method is that recommended by Liston. It consists in passing, by means of long nævus needles, fixed in wooden handles, and having their eyes near their points, double whip-cord ligatures in opposite directions beneath the tumour; then cutting through

Fig. 427.—Syringe for Injecting Nævus.

the nooses, and tying together the contiguous ends of the ligatures until the whole of the growth is encircled and strangled by them. In doing this, a few precautions are necessary : thus, the first *nævus* needle should be passed across the tumour unarmed (Fig. 428), and used to raise up the growth somewhat from the subjacent parts. The second needle, armed as represented in the diagram (Fig. 428), carrying the whip-cord ligature by means of a piece of suture silk, should be passed across the tumour in the opposite direction to, but underneath, the first needle ; the armed needle being withdrawn, the ligature is carried across ; and the first one, having been armed in the same way, carries its noose through the tumour as it is drawn out. The two nooses having then been cut, an assistant must seize, but not draw upon, six of the ligature ends ; the Surgeon next, having divided the intervening bridge of skin, ties rather tightly, in a reef-knot, the two ends that are left hanging

Fig. 428.—Diagram of the Application of Nævus needles.

Fig. 429.—Diagram of Nævus tied.

out ; as soon as he has done this, he proceeds to the next two, and so on to the last (Fig. 429). When he ties these, he must do so with all his force, especially if the tumour be large, as by drawing on them he tightens all the other nooses, and drags the knots towards the centre of the growth, which is thus effectually strangled. He then cuts off the tails of the ligature. After the tumour has sloughed away, which happens in a few days, if it be properly and tightly strangled, the wound is treated on ordinary principles. If the *nævus* be altogether subcutaneous, the skin covering it should not be sacrificed, but, being divided by a crucial incision, may be turned down in four flaps, and the ligature then tied as directed.

In some cases, the *nævus* is so flat and elongated that the application of the quadruple ligature, as above described, cannot include the whole of it. In these circumstances, I have successfully employed the following method in a great number of instances. A long triangular needle is threaded on the middle of a piece of whip-cord about three yards in length ; one half of this is stained black with ink, the other half is left uncoloured. The needle is

inserted through a fold of the sound skin, about a quarter of an inch from one end of the tumour, and transversely to its axis. It is then carried through, until a double tail, at least six inches in length, is left hanging from the point at which it entered ; it is next carried across the base of the tumour, entering and passing out beyond its lateral limits, so as to leave a series of double loops about nine inches in length on each side (Fig. 430). Every one of these loops should be made about three-quarters of an inch apart, including that space of the tumour ; and the last loop should be brought out through a fold of healthy integument beyond the tumour. In this way we have a series of double loops, one *white*, and the other *black*, on each side (Fig. 430). All the *white* loops should now be cut on one side, and the *black* loops on the other, leaving hanging ends of thread of corresponding colours. The tumour may now be strangulated by drawing down and knotting firmly each pair of *white* threads on one side, and each pair of *black* ones on the other. In this way the tumour is divided into segments, each of which is strangulated by a

Fig. 431.—Diagram of Flat and Elongated Nævus tied.

Fig. 430.—Diagram of Ligature of Flat and Elongated Nævus.

naevus and a knot, by *black* nooses and *white* knots on one side, by *white* nooses and *black* knots on the other (Fig. 431).

In some situations in which it is very desirable to save the skin, the naevus may sometimes be cured by *subcutaneous ligature*. This is done by passing a curved naevus needle armed with a strong silk ligature as far as possible round the growth, immediately beneath the skin ; on the eye emerging, the thread is secured and the needle withdrawn. The needle is then passed unarmed so as to include the other half of the tumour ; as soon as its eye appears it is threaded with the end of the ligature and drawn back. The ligature is then tightened, and the naevus thus strangulated subcutaneously. If preferred, the operation can be done with a common suture needle, which can be withdrawn and re-inserted where necessary without being re-threaded. The silk ligature separates by suppuration after a week or ten days.

Attempts have been made to apply subcutaneous ligatures of carbolized silk catgut, and then to push the knot in at the needle-puncture, leaving the thread to be absorbed. This method has not, however, been very successful, as either the ligature excited suppuration and was finally expelled, or after its absorption a return of the growth took place.

**NÆVI IN SPECIAL SITUATIONS.**—**Nævi of the Scalp** are more frequent

than in any other situation, except, perhaps, the face. When occurring on those parts that are covered by hair, they are almost invariably prominent and subcutaneous; when seated on the forehead, or on the bare skin behind the ears, they are often cutaneous. The ordinary subcutaneous *nævus* of the scalp can, as a rule, be safely treated by *excision*. In general, it is better to remove the skin over the *nævus* by an elliptical incision. It is not only troublesome to reflect the skin, but it is likely to be attended with considerable hæmorrhage. In excising the *nævus* with the skin over it the bleeding is rarely difficult to arrest by ligature and pressure. The edges of the wound must be brought together as completely as possible with silver wire and horse-hair sutures.

If the *ligature* be employed care must be taken in passing the needles not to include the epicranial aponeurosis, or troublesome cellulitis and perhaps suppuration may occur beneath it. Those flat *nævi* which are situated behind the ear are best treated with Paquelin's cautery, or by the application of nitric acid.

**Nævus of the Fontanelle** is the most important variety of the scalp *nævus*, and may constitute a somewhat formidable disease. A large purple tumour is situated over the anterior fontanelle, rising and falling with the pulsations of the brain communicated to it, and becoming tense when the child cries. The tumour is evidently close upon the membranes of the brain, and this often deters practitioners from interfering with it; and I have not unfrequently seen cases in which the parents of the child have been counselled not to allow any operation to be practised, lest death should result.

*Electrolysis* or puncture with Paquelin's *cautery* may, however, safely be practised, due care being taken not to penetrate the membrane of the fontanelle. *Excision* of the smaller tumours can quite safely be done, for the growth is in reality altogether confined to the scalp.

If the *ligature* be employed there is some risk of wounding the membranes of the brain in passing the ligatures under the tumour. If *nævus* needles or sharp-pointed instruments of any kind be used, this accident will be very likely to occur; it may always be avoided by operating in the following way. A puncture is made in front of the tumour through the healthy scalp. An eyed probe, armed with a double ligature, is then pushed through this opening across the base of the tumour, and its end is made to project on the opposite side beyond it; here another puncture is made, and the probe and ligature together are drawn through. The same procedure is adopted across the tumour sideways. In this way, a quadruple ligature is passed across the tumour in two opposite directions; the ends are then disengaged, and the ligature is tightened in the ordinary way.

**Nævi of the Face** are of very common occurrence, and usually cause much disfigurement. The treatment to be adopted necessarily varies greatly, according to the nature of the *nævus*, whether cutaneous, subcutaneous, or both; and especially according to its situation. We shall, accordingly, consider the treatment of these vascular growths, as they affect the eyelids, the nose, the cheeks and the lips.

**Nævus of the Eyelids** is usually cutaneous, consisting of a discoloration or staining, as it were, of the lid, without any material swelling. Such a disease is, I think, better left untouched; it cannot, of course, be removed either by the knife or by caustics, without producing worse results; and, as the skin is always deeply involved, milder means are inoperative, or

possibly equally destructive. I have heard of sloughing of the eyelid being occasioned by the use of astringent injections ; though, if the nævus were subcutaneous and constituted a distinct tumour, passing perhaps into the orbit, destruction of the growth by electrolysis is the safest and most efficient mode of treatment.

**Nævus of the Nose** may occur in two situations—at the root, or towards the *alæ* and apex. When seated at the root of the nose, upon the bridge, or at the lower part of the forehead, between and perhaps extending above the eyebrows, it is often subcutaneous, and may attain a very considerable size. In cases of this kind, electrolysis or Paquelin's *cautery* will be found most generally useful. I have also found the *quadruple ligature* a ready means of removal.

In the case of a little girl about three years of age, I removed a mixed nævus as large as a walnut, from this situation, by means of the quadruple ligature, with the most satisfactory result, the resulting cicatrix being remarkably small ; and in another little girl, from the bridge of whose nose I removed a nævus as large as a marble, very little scarring or deformity resulted. When the tip and *alæ* of the nose are affected, the nævus being cutaneous, we can seldom do much to improve the appearance of the patient. In such cases, I have tried breaking down the nævus, and the use of the galvanic cautery, without any material benefit ; the destruction of the tissues soon afterwards leading to deformity. When the nævus is subcutaneous, occupying the tip, *alæ*, and *columna nasi*, electrolysis or the cautery is the means most likely to be of real service.

**Nævi of the Cheeks** may occur in three distinct forms. 1. There may be a simple cutaneous nævus, a mere staining of the skin, a "mother's mark." This admits of no satisfactory treatment in most cases ; and the subject of it must submit to exhibit the characteristic discoloration through life. 2. The elevated cutaneous nævus may be raised above the surface, being of a deep purplish-red or plum colour, and covered with a very thin integument. In this form of the disease, I think that the application of concentrated nitric acid is the best means of extirpation. By one or two applications of the caustic the growth is removed, and a dense white cicatrix, presenting little disfigurement, is left in its place. 3. The nævus may involve the whole thickness of the cheek, being scarcely, if at all, cutaneous. Nævi of this kind cannot, of course, be extirpated, either by the knife, ligature, or caustics, lest the cheek be perforated, and the most serious disfigurement ensue. In such cases we must endeavour to obliterate the structure of the nævus by electrolysis, or by breaking down the structure of the growth with cataract needles or a fine tenotome. I once cured a large and deeply-seated nævus of one cheek, by passing a number of fine silk threads across it in different directions, and gradually breaking it down piece by piece, with a cataract needle ; no disfigurement whatever was left.

**Nævi of the Lips** require different treatment, according as they occupy the margin or have involved the whole substance of these parts. When seated at the margin, as projecting and somewhat pendulous growths, they may very readily be removed by a double or quadruple ligature, according to their size. This was the practice pursued in the case from which the accompanying drawings (Figs. 432, 433) were taken, where a most excellent result was obtained by the use of the ligature, followed at a later period by injection of perchloride of

iron into some of the more widely diffused parts of the growth. When the nævus involves the whole thickness of the lip, such measures are not always available. In these cases electrolysis or puncture with the cautery from the mucous surface, repeated at intervals till the whole growth is consolidated, is perhaps the safest and best treatment.

When the whole substance of the lip is involved, strangulation by means

Fig. 432.—Nævus of Lower Lip:  
Front View.

Fig. 433.—Nævus of Lower  
Lip: Side View.

of the ligature is seldom available, as the amount of sloughing being very great, the child would incur the danger of septic poisoning. In an infant with a very large nævus, including one half of the lip, which I ligatured at the Hospital many years ago, death appeared to result from this cause. One of the most formidable cases of nævus of the lip that I have ever had to do with, and in its results the most satisfactory, was sent to me

Fig. 434.—Large Nævus of Upper Lip:  
Front View.

Fig. 435.—Large Nævus of Upper  
Lip: Side View.

some years ago, by Budd of Barnstaple. The patient, a little girl five years old, was noticed at birth to have a red streak on the right side of the upper lip; this rapidly developed into a large tumid purple nævus, which, when the case came under my observation, was about the size of a large walnut, involving the whole of the structures of the lip, from the cutaneous to the mucous surfaces; it was of a deep mulberry colour, and extended from the median line of the lip to the angle of the mouth

(Figs. 434, 435). The integuments covering this growth were exceedingly thin, and the tumour itself was in the highest degree vascular and active. Excision appeared to be out of the question; the ligature presented little to recommend it; injections with the perchloride of iron and the introduction of setons were successively tried, but neither of these means produced any effect on the tumour, which commenced to extend upwards into the nostril. I accordingly determined to use caustics. Nitric acid was first employed; but, as this did not produce a sufficiently deep impression on the growth, I had recourse to the potassa cum calce. By means of this, the tumour was gradually removed, the hæmorrhage which occasionally resulted being restrained by pressure. Notwithstanding the amount of tissue destroyed, the resulting cicatrix was small, resembling that of a badly-united hare-lip. Three years afterwards, the child was brought to me again, and I was much struck by the wonderful improvement that had taken place since the removal of the nævus. The lip was smooth, the cicatrix in a great degree worn out, and comparatively little disfigurement was left in the countenance of an exceedingly pretty and engaging child. Finding, however, that the lip was still drawn or tucked in by a very dense band of cicatricial tissue, which caused a deep depression of the ala of the nose, on that side, I divided this, and the result was most satisfactory.

It has been recommended when the growth invades the substance of the lip deeply for a limited extent, to remove it by an operation somewhat similar to that for the removal of an epithelioma; the whole substance of the lip being cut through widely on each side, and the sides of the wound brought together with hare-lip pins. Such operations are, however, not advisable, as apart from the danger of hæmorrhage, the disease can always be cured by some of the means above described, without leaving the amount of deformity that would result from its removal by the knife.

**Nævus of the Tongue** is of rare occurrence. It is usually best treated with a fine-pointed cautery, but in extensive cases it may be advisable to excise the affected portion by a  $\Lambda$ -shaped incision. In the case from which Fig. 436 was taken, I removed the front of the tongue with the *écraseur*.

Fig. 436.—Nævus of Tongue.

**Nævi of the Organs of Generation** are occasionally met with in the female, but rarely in the male. The only instance of *Nævus of the Penis* with which I have met occurred in the case of a gentleman thirty-two years of age, who consulted me some years ago for a growth of this kind, as large as a walnut, situated under the reflection of the preputial mucous membrane. It had existed for many years without causing any annoyance, but, as it had of late begun to enlarge, and occasionally to bleed, he was desirous of having it removed. This I did by applying the quadruple ligature, after having dissected the mucous membrane down. Excision would probably be as a rule the best treatment in such cases.

**Nævi of the Vulva** are by no means unfrequent. They are usually venous, often attain a large size, and may sometimes involve the inside of the thigh, or the perineum, as well as the vulva. When the growth is confined to the vulva, it is best removed by the ligature. Some time ago, I removed in this way a large pendulous venous nævus, as large as two or three flattened walnuts, from the left labium of a little girl six years of age. In this case, I found it most convenient to employ the continuous ligature. The same procedure was had recourse to in order to extirpate a large nævus from the labium of a child three years of age; but in this case the disease extended to the integuments of the perineum and inner side of the thigh, and was here removed by the application of strong nitric acid, after the larger growth had separated.

**NÆVOID LIPOMA.**—This is a form of nævus which I have occasionally seen, but which does not appear to have attracted much notice, although Nélaton speaks of it, and Billroth says that in lipoma he has several times met with cavernous dilatation of the veins. It is a tumour in which the nævoid structure is conjoined with a fatty growth usually more fibrous than an ordinary lipoma. This disease is invariably seated upon the nates, back, or thigh. It occurs as a smooth, doughy, indolent tumour, incompressible, not varying in size or shape, without heat, thrill, or pulsation of any kind, possibly having a few veins ramifying over its surface, but no distinct vascular appearance. It is usually congenital, or has been noticed in early childhood; and it continues without any very material change in shape, size, or appearance, until the inconvenience or deformity occasioned by it necessitates its removal. This is best effected by the knife. After removal, the tumour will be found to be composed of a mass of fibrous fat, having a large number of veins ramifying through it, so as to constitute a distinct vascular element, often communicating with small cysts containing a bloody fluid. The tumour has occasionally a tendency to recur after removal. In one case I operated three times for the removal of a large growth of this description, situated on the buttock, and extending forward towards the perineum. The first operation was performed in 1851; the second in 1856; and the patient, then eighteen years of age, again presented himself in 1863 with a recurrence of the growth in an ulcerated state, in the cicatrix of the former operations. The situation in which I have seen such tumours occur, where they gave rise to most inconvenience, and where their removal has required the greatest care, has been the anterior part of the thigh, just below Poupart's ligament, close upon and almost in connexion with the femoral vessels. In a case of this description, which was sent to me by Edwards of Antigua, the patient, a gentleman of that island, had suffered for some years from a chronic solid œdema of one of his legs, apparently dependent upon the pressure exercised upon the saphena and femoral veins by an elongated indolent tumour just below Poupart's ligament, and over the course of these vessels. This tumour had existed from childhood, and presented the signs that have just been given as characteristic of the disease under consideration. It was removed by an incision parallel to Poupart's ligament, some careful dissection being required to separate it from the femoral sheath, more particularly towards the inner side, where a prolongation of the tumour dipped down by the side of the femoral vein, compressing that vessel, and thus causing the œdema of the limb. After removal, the tumour was found to consist of a mass of dense adipose tissue, with much

vascular structure intermixed, and some small cysts. The œdema gradually subsided ; and when the patient left England, about three months after the operation, the limb had nearly regained its normal size.

#### HÆMORRHAGIC DIATHESIS, OR HÆMOPHILIA.

In connexion with diseases of the blood-vessels it may be stated that in some constitutional conditions it is found, though fortunately very rarely, that there is a great tendency to very troublesome, indeed almost uncontrollable, bleeding from slight wounds. An abnormal tendency to bleed is sometimes observed in persons who are "out of condition," and whose tissues are soft and flaccid. They bleed freely from slight wounds, and bruise extensively from trivial blows. In these cases the bleeding appears to be maintained by the want of tone preventing the proper contraction of the divided or torn vessels ; and the tendency to hæmorrhage will vary at different times in the same person according as the state of his health improves or deteriorates. In other cases abnormal bleeding may be due to diminution in the normal coagulability of the blood. This state is sometimes met with in scurvy, chronic jaundice, and albuminuria. The disease known as **Hæmophilia** or **Hæmorrhagic Diathesis** is quite independent of such conditions as these. It is a peculiar constitutional state always congenital, and most frequently hereditary, especially in the male line. In some families the males only have been affected, and the diathesis has been transmitted in the second or third generation through females ; who, being themselves unaffected by it, have had male children who were the subjects of the disease. The diathesis occurs in persons without any other apparent derangement of health, or morbid condition, innate or acquired, to account for it. In such cases the family peculiarity is usually recognized, and well known to those liable to it.

The only constant sign of the diathesis is the free and often almost uncontrollable bleeding that takes place from trivial wounds ; the hæmorrhage resulting from the extraction of a tooth, the opening of an abscess, lancing the gums, or some equally slight unimportant surgical procedure, having sometimes proved fatal. The blood does not flow in a jet, but continues to trickle in an oozing stream, apparently from the capillaries rather than from the larger vessels of the part. In these cases also there is a great tendency to extensive ecchymosis from very slight contusions.

In these families of bleeders, it is scarcely necessary to say that it is imperative to be careful to make no surgical wounds, even of the most trivial character, if they can possibly be avoided. Above all, the extraction of teeth must be avoided. It is after this slight operation that the most uncontrollable and fatal hæmorrhages have occurred. The hæmorrhages, though usually traumatic, may be spontaneous ; they then usually proceed from the nose, the bowel, the kidney, or the subcutaneous connective tissue. In women they assume the character of profuse and uncontrollable menorrhagia. The hæmorrhages are accompanied by the symptoms described at p. 409, Vol. I., as characterizing excessive loss of blood ; and after their cessation the patient remains anæmic usually for many weeks or months. The quantity of blood lost is often enormous, amounting in some cases to several pounds in the twenty-four hours.

The tendency to bleeding is chiefly from recent wounds or healthy mucous

membranes, and sometimes does not occur from diseased surfaces from which it presumably would be likely to happen. Thus a member of one of the three families of bleeders, who have frequently been inmates of University College Hospital, died lately of phthisis, with large cavities in the lungs. A few weeks previously he had nearly died of hæmorrhage after the extraction of a tooth, but he had never suffered from serious hæmoptysis. In another case the patient passed through an attack of typhoid fever without serious hæmorrhage. In another a large slough formed in the skin after the application of perchloride of iron, cold and pressure to arrest hæmorrhage from a punctured wound of the leg, yet the slough separated, and the large granulating sore healed without any recurrence of the bleeding.

Formerly it was supposed that females were exempt from hæmophilia. But Wickham Legg, to whom we are indebted for an excellent monograph on this condition, states that this assumption can no longer be maintained, although women are far less disposed to the disease than men; that they present few instances of the more typical forms of the disease, and that it is less fatal in them than in men. Most of the fatal cases in women have occurred by hæmorrhage from the genital organs, and Legg quotes a case from Wachsmuth, "where the rupture of the hymen on the marriage-night caused the death of the bride from hæmorrhage."

A frequent symptom accompanying this diathesis is a painful and sudden swelling of one or more joints, occurring either spontaneously, or as the result of some slight injury. The swelling is the result of an effusion of blood and synovia into the synovial membrane. It is usually accompanied by some slight febrile disturbance. It may last only a few days or may persist for months. The joint is often permanently weakened, and relapses are frequent during the cure.

**Pathology.**—Little if anything is known with certainty about the nature of this peculiar affection. It has been stated that in some cases the inner coat of the arteries has been found abnormally thin, and degenerative changes have been observed in the endothelium, but the observations are not sufficiently numerous or uniform for any theory to be founded upon them. From the influence exerted by cold in the arrest of the bleeding, it may reasonably be suspected that a want of proper contractility in the arteries has some influence in causing the bleeding. With regard to the condition of the blood, varying statements have been made; it has been said to be watery, deficient in corpuscles, and uncoagulable. In the cases which have been admitted into University College Hospital, however, the blood in the earlier stages of the hæmorrhage coagulated healthily and was of good colour, though after great loss the tint became paler and the coagulum less firm. Accurate analyses of the blood from bleeders are still wanting. It has been suggested as another explanation of the disease that its real cause is an excess of blood, but of this also there is no definite evidence. It would appear then that the only facts of importance that we at present possess to throw light on the cause of hæmophilia are: that it is hereditary; that it is far more frequent in males than in females; and that it is congenital, and may occur in all races and in all countries.

**Treatment.**—In true hæmophilia no remedies appear to exercise the slightest influence over the diathesis. At the same time, it would be wise for the subject of this unfortunate condition to attend to those ordinary

rules of health, the neglect of which, by lowering his "condition," might favour the tendency to bleed. Legg especially recommends the use of cold baths of plain, sea, or chalybeate waters, residence in a dry air, and the use of warm clothing. The preparations of iron are usually given in a routine way, but it is doubtful if they have ever been of service in preventing the hæmorrhages; they certainly never have arrested them, though they may be of use in removing the anæmic state left after a copious bleeding. Ergot has been given during the bleeding in many cases, but without evident effect.

The *Local Treatment* is that on which most dependence will necessarily be placed. It consists in the use of three means—viz., Pressure, Styptics, and Cold.

**Pressure** is to be relied on only in one form of hæmophilic bleeding—viz., the continuous hæmorrhage from the socket of a tooth after extraction. In these cases the cavity should be cleared out and carefully plugged from the bottom by means of lint or agaric, the whole retained by means of a piece of cork and a gutta-percha cap to fit over the neighbouring teeth, and compressed by a bandage applied under the chin against those in the sound jaw. When the hæmorrhage occurs from the soft parts, pressure must be used with great caution lest sloughing occur; the integuments being extremely liable to give way extensively under very moderate pressure, large subcutaneous extravasation developing at the same time, and thus increasing materially the danger of the case and the local mischief.

Compression of the main artery of the limb is useless, and open to the objection that it may cause the development of ecchymoses and subcutaneous hæmorrhages.

**Styptics** of all kinds have been used as a matter of course, and the perchloride of iron has enjoyed especial favour. I have used and seen it used frequently, and can safely say that I have never seen any permanent benefit from its application in these cases. Indeed, great evil has often resulted from the inflammation excited by the application of styptics of any kind. The parts become swollen and slough, and as the sloughs separate the oozing may recommence from the raw surface, and the same process has to be gone through again. A. E. Wright has suggested the application of a one per cent. solution of calcium chloride to which some fibrin-ferment, obtained by extracting washed fibrin with water, may be added; or the styptic described in Vol. I. p. 422, may be tried.

The **actual Caustery** presents the same disadvantages as ordinary styptics. It may temporarily arrest the bleeding, but inflammation is set up in the parts beyond the limit of the eschar, and this on separating leaves an extended ulcerating surface which may bleed again, perhaps more freely than before.

The continued application of **Cold** appears to arrest hæmophilic bleeding more effectually than any other means, and this circumstance would lead to the belief that the hæmorrhage is due to want of contractility in the smaller arteries rather than to want of coagulability in the blood. The cold may be applied by means of irrigation of iced water, as was done successfully by Marshall, or by the application of ice either directly to the part or laid upon a sponge covering it, as has been done in some of the cases of hæmophilia occurring at University College Hospital. Simple water may be used, or a

weak solution of boric acid. If the bleeding wound be in the extremities, the limb should be elevated and kept at rest on a splint.

The Surgeon has already been cautioned as to the inexpediency of performing any operation, except under circumstances of the most urgent necessity, on any member of a family of bleeders, or on an individual known to be the subject of hæmophilia. Should an operative procedure become necessary, it should, if possible, be carried out with Paquelin's thermo-cautery, or the galvanic *écraseur*.

## CHAPTER XLII.

## DISEASES OF ARTERIES.

ARTERIES are liable to numerous diseases which derive great importance from the effects they produce, both upon the vessels themselves and upon the parts to which they carry blood. Amongst the most important are the various forms of inflammation or arteritis. The inflammatory affections of arteries are divided first into two classes, viz., those resulting from injury, and those arising from general or local causes not of a traumatic nature. Inflammation of the arteries is divided also into endarteritis, in which it affects primarily or chiefly the internal coat, and peri-arteritis, in which the process commences in the outer coat or sheath. The term "mes-arteritis" has also been suggested for inflammation of the middle coat, but it is of little use, as no true inflammatory affection commences in that part of the vessel. Some forms of arteritis are named from the cause of the disease, as syphilitic or embolic. As in other structures, the inflammatory process may be acute or chronic. In addition to the above diseases, arteries suffer from various degenerative changes, some of which are primary, affecting the original tissues of the vessels, others are secondary, the degeneration taking place chiefly in the products of a chronic inflammatory process. These various processes are still further complicated by secondary effects, such as the formation of aneurism, from the diseased walls of the artery yielding before the pressure of the blood, and thrombosis of the affected vessel followed by its obliteration, and sometimes by embolism and gangrene.

In discussing the diseases of arteries, it will be most convenient to consider first the various forms of inflammation; secondly, the degenerations; and lastly, the more remote effects of these changes.

## ACUTE INFLAMMATION OF ARTERIES.

**Acute Arteritis** of idiopathic origin, that is to say, arising as an independent affection for which no evident cause can be found, was formerly believed to be a comparatively common disease. It was supposed to affect the inner coat, spreading along the vessel in the direction of the circulation, and from this fact it was spoken of as diffuse or erysipelatous. It is now known, however, that no such affection really exists, and that the error arose partly from assuming that thrombosis is invariably evidence of previous inflammation of the affected vessel, and partly from mistaking for the redness of inflammation the staining of the intima, so often observed as the result of changes in the blood with disintegration of the red corpuscles, which may occur during life in acute forms of blood-poisoning such as septicæmia or malignant fevers, or after death as the result of putrefaction.

**Traumatic Arteritis.**—Simple acute traumatic inflammation limited to

the part injured and showing no tendency to extension, is familiar to every Surgeon in connexion with contusion, laceration, wound, or ligature of arteries; for in the early period of repair after any of these injuries, inflammatory exudation from the vasa vasorum forms an essential part of the process. For a description of this condition, the reader is referred to Vol. I., Chap. XIV.

**Arteritis by Extension,** from infective inflammation or ulceration of the tissues surrounding the vessel, has already been described as one of the dangers accompanying these processes. In inflammation affecting an artery in this way, the process is the same as in other tissues. The vessels of the outer coat are dilated, inflammatory exudation with migration of corpuscles takes place, and the wandering cells infiltrate the coats of the artery, which become swollen and softened. The process spreads from the outer to the inner coat, the endothelium separates, and fibrin is deposited upon the diseased surface. In the smaller arteries complete thrombosis takes place, and the clot extends upwards to the nearest branch beyond the inflamed part of the vessel, and may then undergo the changes already described as occurring in the permanent closure of an artery (Vol. I., Wounds of Arteries), and hæmorrhage is thus prevented. In arteries above the size of the radial, however, the closure of the vessel is frequently not accomplished before the coats are so far softened as to give way before the pressure of the blood, and thus fatal hæmorrhage may result. This is all the more likely to occur when the inflammation and subsequent ulceration affect a limited portion of one side only of the artery, as in those cases in which it is due to the contact of an irritating foreign body, such as a sequestrum. In the larger arteries complete thrombosis occurs much less readily than in smaller vessels or in veins, the rapidity of the flow of the blood being unfavourable to the adhesion of the white corpuscles which is the first step in thrombosis.

In arteries which have been divided and secured by ligature or otherwise, the extension of unhealthy inflammation from the wound to the exposed end of the vessel, followed by softening of its coats, and disintegration of the contained clot is the commonest cause of secondary hæmorrhage.

**Embolic Arteritis.**—Moxon has pointed out that a form of acute arteritis resulting in softening and swelling of the arterial wall, thus leading to the formation of an aneurism or to rupture of the vessel, is in rare cases the result of the lodgment of an embolus. A simple fibrinous embolus lodging in an artery merely obliterates the vessel without causing softening of its coats. In order that inflammatory softening may occur, it is necessary that the embolus should be derived from a part which is the seat of some infective inflammation, and that it should carry with it the unhealthy products of the process. Embolic arteritis is most likely to occur in the somewhat rare affection known as ulcerative or infective endocarditis, but it has also been known to follow embolism during the course of an ordinary case of acute rheumatism. Localised arteritis arising in this way is believed to be the most common, if not the sole cause of spontaneous aneurisms in children, and in the smaller vessels of the extremities in adults. Rushton Parker has recorded a case which well illustrates this form of disease. A boy, aged 14, during an attack of acute rheumatism was suddenly seized with pain in the forearm, followed by swelling of the limb. The general swelling soon subsided, leaving a deeply-seated circumscribed tumour, which steadily increased in size for the

next four months. On laying this open a cavity was exposed containing more than a pound of dark clotted blood, and the anterior interosseous artery was found to communicate with it by an opening a quarter of an inch in length. The vessel was successfully ligatured above and below the opening, and the boy recovered. At the time of the operation there was a loud double aortic murmur. Langton and Bowly have recorded a case in which as a consequence of the lodgment of emboli from the valves of the heart in ulcerative endocarditis, aneurisms formed at the bend of the elbow and in the popliteal space, necessitating the ligature of the brachial and femoral arteries. The patient died eight weeks afterwards from the effects of an embolus lodged in the brain.

**Acute Endarteritis.**—Cornil and Ranvier describe under this name an affection of the inner coat, met with chiefly in the aorta, but occasionally also in smaller vessels, especially near wounds. It is characterized, to the naked eye, by prominent patches formed by a swelling of the intima. They are circular or oval in outline, and seldom exceed half an inch in diameter, though both their form and their size may be altered by the coalescence of neighbouring patches. They are pale pink in colour, and semi-transparent or opalescent; in consistence, they are soft and elastic, almost gelatinous. The internal surface has often lost its polish, in consequence of the irregularity of the swelling, but its endothelial covering is usually intact. The middle coat beneath the patch appears usually to be somewhat swollen, and this condition is more marked in the adventitia. Microscopic examination shows that the swelling is due to an accumulation of small cells, either round or slightly irregular in outline, between the fibres of the sub-endothelial connective tissue and the elastic layers of the inner coat. These cells have a distinct nucleus surrounded by a small quantity of protoplasm, and show signs of active growth. Cornil and Ranvier believe they are produced by proliferation of the original cells of the part. The swelling of the external coat is found to be due to the presence of numerous cells of new formation separating the fibres of the connective tissue.

The conditions under which acute endarteritis occurs are not clearly determined, but as every intermediate condition between it and the chronic form immediately to be described, is to be met with, sometimes even in the same vessel, it seems to be nothing more than the same process increased in intensity.

**Periarteritis.**—By periarteritis is meant an inflammation commencing in the outer coat or sheath of the artery. If we exclude arteritis by extension from surrounding tissues and traumatic arteritis, periarteritis is a rare disease. Charcot and Bouchard have described such an affection in the vessels of the brain, commencing as an accumulation of small round cells in the perivascular sheaths; these penetrate the coats from without and lead to softening, frequently followed by the formation of minute aneurisms and final rupture. It is a senile disease, and according to Charcot a common cause of apoplexy.

An affection of the arteries of an uncertain nature not causing obliteration has been observed, which, from its giving rise to acute pain and tenderness with some swelling in the line of the vessel, must be supposed to be inflammatory. A case of this kind was recorded by J. H. Morgan, in the *Transactions of the Clinical Society* for 1881. The patient, a man aged 46,

was attacked with severe pain in the line of the right femoral artery; the vessel was acutely tender, but there was no redness of the skin covering it. The condition was at first limited to a few inches of the artery near the groin, but gradually extended to the popliteal space and leg. Slight œdema and some swelling of the lymphatic glands became apparent when the disease reached the leg. The vessel pulsated forcibly and there was no thrombosis. The man had some years previously suffered from a similar affection of the opposite leg, and while still under observation, the right brachial and carotid were successively affected. Altogether the second attack lasted over five months. It was not apparently due to syphilis, gout, or rheumatism. From the absence of thrombosis it would seem probable that the disease was a periarteritis.

#### CHRONIC INFLAMMATION OF ARTERIES.

**Chronic Endarteritis, Arteritis Deformans, Atheroma.**—This is by far the most common disease to which arteries are liable; in fact, it is very rare after middle life to find it completely absent in the larger vessels. It occurs in its most marked form in the aorta and the large arteries of the neck, abdomen, the upper parts of the limbs, and the base of the brain. It is less commonly seen in the smaller vessels, in which the muscular coat is more fully developed.

Fig. 437.—Atheromatous patch in Aorta. The process has advanced to the formation of a so-called "atheromatous ulcer."

Chronic endarteritis first appears as pale yellowish patches or streaks, smooth, slightly elevated above the surface, and evidently seated in the deeper layers of the inner coat. They are irregular in outline, their long diameter is usually in the line of the vessel's course, but they show a special predilection for the mouths of the branches leaving the main trunk, round which they form annular elevations. Their outline subsequently becomes more irregular by the coalescence of neighbouring patches. As the disease advances, the patches become more elevated, often reaching a line or more in thickness. At this stage they are grey, semi-transparent or opalescent, and inelastic, some-

times almost cartilaginous in appearance and consistence. This condition is, however, speedily followed, before the patches have reached more than half an inch in diameter, by a change to an opaque yellow colour, the alteration in tint commencing in the central parts. This change is due to fatty degeneration, and is accompanied by some loss of toughness. The further progress may be in one of two directions: the growth may soften and break down; or it may calcify. When softening takes place the patch becomes converted into a pulsatous or cheesy mass, and even sometimes undergoes complete liquefaction into a yellow creamy fluid, which has been mistaken for true pus, and termed an "*atheromatous abscess*." It is this change that led

to the term "atheroma" being applied to the disease, the products of the softening of the patch resembling the contents of an atheromatous cyst of the skin. The term is now often incorrectly extended to all stages of chronic endarteritis.

When the process reaches the more advanced stages the middle coat is affected, first by chronic inflammation, and subsequently by softening. At the same time considerable thickening of the external coat takes place by the formation of dense fibroid tissue which is not prone to fatty degeneration and softening. Up to this point the fatty patch is covered by the most internal layers of the intima and the endothelium, which are not affected by the chronic inflammatory process, but after complete softening these give way, and the atheromatous fluid is discharged into the circulation, leaving the remains of the patch exposed to the blood-stream. The raw surface thus formed is the so-called "*atheromatous ulcer*" (Fig. 437). The *débris* which enter the circulation are carried on and lodge in the capillaries, but not possessing any irritating properties they give rise to no evil consequences. Although during this process a considerable part of the inner and middle coats is lost, perforation or rupture of the artery rarely takes place, and it is only in exceptional cases that the blood forces its way amongst the coats of the diseased vessel. This is due to the fact that at the margins of the patch the chronic inflammatory process has led to firm matting together of the coats of the artery. At the same time the thickening and induration of the external coat prevent perforation. It is especially opposite the deeper and more eroded atheromatous patches that this consolidation of the external coat takes place. The change, although described as a chronic inflammation, is strictly conservative in character. The new growth of fibroid tissue is not confined to the external coat, but extends to the sheath of the vessel, and, by soldering it to the contained artery, greatly adds to the strength of the vascular wall.

Although perforation is thus prevented, the new tissue but imperfectly represents the normal structures of the coats of an artery, as it is entirely wanting in elasticity. Consequently it is very apt to yield slowly to the pressure of the blood, and thus lead to the formation of a sacculated aneurism, the mouth of which will correspond to the damaged portion of the wall of the vessel.

Complete softening, with the formation of an atheromatous ulcer, is not by any means a necessary consequence of fatty degeneration of the patches resulting from chronic endarteritis. In many cases the new tissue, after degenerating, remains as a firm, yellow, opaque mass, and may undergo no further change, but most commonly lime salts are deposited in it, and it gradually becomes converted into a hard calcareous plate, over which the superficial layers of the inner coat with the endothelium may remain unbroken. Sometimes, however, these seem to wear away and the calcareous plate comes in direct contact with the blood-stream. This change was formerly described as "*ossification of the arteries*," but it need not be said that no true bone is formed. From the arrangement of the calcareous matter in plates corresponding to the atheromatous patches in which the lime salts have been deposited, this change has received the name of *laminar ossification*.

Microscopic examination of an atheromatous artery in the early stage of the

disease shows that the morbid change commences in the deeper layers of the inner coat, the affected area being bounded externally by the yellow elastic lamina. The flattened cells which lie between the laminae of connective tissue of which the deeper part of the intima is chiefly composed proliferate. The new cells are arranged in lines between the laminae. With the proliferation of the cells there is a growth of new laminae of connective tissue closely resembling that of the healthy inner coat, both in appearance and in arrangement, but they are altogether inelastic. The relative amount of cells and fibrous intercellular substance varies in different cases, but the chief bulk of the new tissue is always composed of the latter. The cells are small, rounded or slightly flattened, and contain a nucleus of considerable size, round which it is often difficult to recognize any protoplasm. No vessels penetrate the new tissue, and consequently when it reaches a certain stage of development the central parts are but imperfectly nourished, and degeneration commences. The cells become shrivelled and granular, and fatty granules also appear in the intercellular substance. At a later stage calcareous granules may also make

Fig. 438.—Fatty debris, oil globules and cholesterine crystals from a softened atheromatous patch.

their appearance. If softening takes place, the fat granules increase in quantity, and solution of the intercellular substance follows. If complete liquefaction takes place, the atheromatous fluid is found under the microscope to be composed chiefly of fatty debris and oil globules, and very frequently it contains plates of cholesterine (Fig. 438). The accompanying drawing (Fig. 439) illustrates the structure of an atheromatous patch very well.

The changes in the middle and outer coats require but little notice. The middle coat in the later stages is often invaded by a growth similar in character and structure to that which originally started in the inner coat. In fact, it seems to be

an extension of the same growth, the true structures of the middle coat being atrophied from pressure. The outer coat shows a growth of new fibrous tissue containing a number of small round, or elongated cells.

**Nature and Causes.**—The views as to the nature of the disease have undergone various changes, but at the present time it is almost universally regarded as a chronic inflammatory process, characterized by overgrowth of the affected tissue followed by degeneration. Galliver was long ago inclined to this opinion, and it has been especially insisted on by Virchow, Billroth, and Moxon. That it belongs to the class of morbid processes almost universally spoken of as chronic inflammations may be said now to be generally accepted, but the difference between these and acute inflammation is so marked that probably, with the advance of pathological knowledge, a complete separation will be made between them.

The most important cause of chronic endarteritis is mechanical strain. This may be constant, as the result of abnormal resistance in the capillaries or smaller arteries, or intermittent, such as occurs during violent exertion, in which, while the heart is beating forcibly, the resistance to the circulation is increased by the contraction of the muscles. Moxon has brought forward abundant evidence in proof of this theory. He points out that atheroma occurs more constantly and at an earlier period in males than in females, and

that when extensive atheroma is met with in women, it will usually be found that they have been engaged in hard manual labour. In men, the most marked examples are met with in those whose occupations have involved violent physical exertion. In wasting diseases, in which the quantity of blood is diminished and the arterial tension reduced, atheroma is seldom met with, and in the pulmonary arteries, in which the pressure is much less than in the systemic vessels, chronic endarteritis is rare, being observed only in those cases in which the right heart is hypertrophied in consequence of chronic bronchitis and emphysema, or obstruction at the mitral orifice. The disease first shows itself, moreover, in those parts which are exposed to the greatest strain, as in the arch of the aorta, and at the points at which large branches are given off or a trunk bifurcates. It is common also to find the disease

FIG. 100.—Atheroma of Aorta. e, Elastic lamina; m, middle coat; l, internal coat; f, the new growth undergoing fatty degeneration.

are advanced in those situations in which the artery is placed in close proximity to a bone, as in the femoral at the brim of the pelvis. The fact that chronic endarteritis is always more marked in the vessels of the lower limb than in those of the upper may also be explained by the pressure being greater in the most dependent parts while the body is in the erect position.

Among the constitutional affections which predispose most powerfully to the development of atheroma is *chronic Bright's disease*, with the granular contracted kidney. Gull and Sutton demonstrated that this disease is associated with a general change in the smaller arteries and capillaries, to which they gave the name of *arterio-capillary fibrosis*. It is characterized by a fibroid thickening of the external coat of the smaller arteries. In the *congested* kidney, Johnson has described a thickening of the walls of the smaller arteries, which he believes to be due chiefly to the hypertrophy of the muscular coat. The nature of these changes and their extent are still matters of dispute; but whatever the exact pathological change may be, it is beyond

a doubt that it causes considerable obstruction to the circulation, a fact which is proved by the hypertrophy of the heart that accompanies the disease and the evidence of increased arterial tension as indicated by the sphygmograph.—The granular contracted kidney and the general vascular changes associated with it are very commonly the result of *gout*, so much so that this form of Bright's disease is often termed the "gouty kidney." Gout is usually the result of an abuse of alcoholic stimulants, and thus *habitual alcoholic excess* comes indirectly to be an important cause of chronic endarteritis.

The influence of *syphilis* in the causation of atheroma is a more doubtful point. Aitken attaches great importance to it. The effect of syphilis in causing disease of the smaller arteries, and fibroid induration of organs and tissues has already been pointed out (see Syphilis, Vol. I.), and it is evident that these changes would tend to obstruct the circulation and thus cause increased arterial tension. Whether it acts more directly as a cause of atheroma is uncertain.

The most important predisposing cause of chronic endarteritis is *old age*. After a certain period of life the arteries in common with other tissues become impaired in structure. The impairment manifests itself chiefly by a diminution in the normal elasticity of the coats, so that they become less capable of withstanding any strain to which they may be subjected. So frequent, and indeed constant, are these transformations of the arterial coats during the decline of life, that they may be considered the natural result of the diminution of the nutrient activity consequent upon advance in years. Gmelin found that there is a progressive increase in the earthy matters contained in the coats of healthy arteries as the individual advances in life. Thus he ascertained that the ash of the arteries of a newly-born child yields 0.86 per cent. of phosphate of lime; the healthy arteries of an adult 1.25; and those of an old man 2.77 of the same salt; whilst the calcified arteries of an aged man contain 4.01. There is no precise period of life at which these changes set in; old age is a relative term, and, as soon as the system has passed its full maturity, in whatever year of life this may happen, there is a tendency for these degenerative changes to take place. The tendency to early degeneration of arteries is frequently hereditary.

**Effects of Chronic Endarteritis.**—As a consequence of the loss of elasticity resulting from the chronic inflammatory and degenerative changes in the coats of the artery, it usually yields more or less before the distending force of the heart. This change is most marked in the aorta and its primary divisions, but is occasionally seen in the femoral and brachial arteries. The dilatation may be regular, or pouch-like projections may form here and there. At the same time the vessel is often somewhat elongated so as to assume a tortuous form. It is in consequence of these changes that the name *arteritis deformans* was given to this disease by Virchow. The interior of the dilated vessel is rough and irregular in consequence of the projection of the atheromatous patches; when softening has taken place, "atheromatous ulcers" may be scattered here and there over the surface, and in other cases it may be paved with closely-set calcareous plates. When the dilatation reaches a certain degree and is limited to a definite area, the condition is described as a fusiform aneurism, the distinction between that and simple dilatation being only one of degree (see Aneurism).

The loss of elasticity in the coats seriously interferes with the circulation through distant parts, as the natural storage of the heart's force in the elastic walls of the larger vessels by which the continuous flow between one systole and another is maintained is no longer possible. The circulation in the extremities is, therefore, usually feeble, and the nutrition of the parts correspondingly imperfect.

*Narrowing or Occlusion of the Branches leaving the Atheromatous Trunk* is by no means uncommon. As before stated, the orifices of the branches from the main trunk are common seats of the earliest atheromatous patches. The thickening of the intima may take place in a ring round the mouth of the vessel and thus gradually narrow it. The coincident thickening of the outer coat may still further contract the orifice. When complete obliteration occurs the final obstruction probably takes place by the formation of a thrombus in the diseased artery immediately above the narrowed orifice. Complete obliteration is most common in those cases in which the dilatation of the main trunk has reached such a degree as to merit the name of a fusiform aneurism. In a case in University College Hospital a few years ago, in which the left carotid was tied for aneurism of the innominate artery and the arch of the aorta with an immediately fatal result, it was found that the right subclavian was obliterated where it left the dilated innominate, the right carotid was pervious, but pressed on by the aneurism, and the aortic opening of the left subclavian was completely closed; thus the artery which was tied was the only vessel carrying blood to the brain. Narrowing of the coronary arteries by an atheromatous ring at their orifices is a common cause of fatty heart.

*Thrombosis* is an occasional consequence of atheroma. So long as the patch is covered by an unbroken layer of the inner coat with its endothelial covering, there is no tendency for coagulation to take place upon it. When, however, the patch has softened and has been discharged into the circulation, leaving an "atheromatous ulcer," or when the thin covering over a calcareous plate has been worn away, the diseased structures come into direct contact with the blood. If the surface is tolerably smooth, the rush of blood past the diseased patch is so rapid that adhesion of the corpuscles is barely possible and consequently no thrombosis results; but in pouch-like dilatations it readily takes place. In the same way it may occur in a very dilated vessel if the heart's action is unusually feeble. A clot thus formed may gradually increase in size till it fills the whole vessel, but more commonly after reaching a certain bulk it is washed away and carried on as an *embolus* to some distant part. If it be of sufficient size to obstruct a main artery of one of the limbs at its bifurcation, gangrene will frequently result. Smaller fragments lodging in the extremities usually produce no important effects, the anastomosing circulation being sufficient to take the place of the obstructed vessel. If lodging in one of the solid viscera, it gives rise to a hæmorrhagic infarct (see Vol. I., p. 981), but does not as a rule cause any serious consequences.

**Syphilitic Endarteritis** has already been described (Vol. I., pp. 1132 and 1134).

**Arteritis Obliterans** (Friedländer). **Endarteritis Proliferans** (Von Winiwarter).—Under these names have been described certain rare cases in which obliteration of arteries takes place as the result of inflammatory changes in their coats, not evidently dependent on syphilis, embolism or injury. Similar changes have also been noted in the veins. The disease usually runs

a chronic course, and may cause spontaneous gangrene of the parts supplied by the affected vessel. The symptoms will perhaps best be illustrated by quoting a typical case recorded by Pearce Gould. The patient was a brick-maker, aged 19. In May, 1883, the fingers of his right hand became congested and sometimes dead white, with much sickening pain. After a few weeks' rest he improved, but soon relapsed on returning to work. After some months the pain extended into the forearm, and completely incapacitated him from working. He came under Gould's observation in October, 1883. At that time the right forearm and hand were cold and somewhat wasted, and he suffered much pain, especially at night. The brachial artery was harder than natural, and pulsated more feebly than on the opposite side. The radial could be felt as a solid cord. There was dry gangrene of the tips of three fingers. No constitutional affection was found to account for the condition. Two weeks afterwards the pain increased till it became agonizing, requiring hypodermic injections of morphia for its relief. At this time there was slight elevation of temperature. The brachial artery then became converted into a pulseless cord to within one inch of the *teres major*. Soon after, the subclavian artery was found to be prominent. In December the pain gradually subsided, and one month after the man was apparently well. The brachial artery remained a solid cord, and the first joint of the thumb and that of the index finger separated after becoming mummified (see *Trans. Clin. Soc.* 1884). This patient was exhibited again in October, 1886. He had worked as a labourer till the previous April, when he was attacked with numbness of the right arm and severe headache which had persisted ever since. In June he suddenly lost power in the left arm, and became unconscious the same evening. From this attack he slowly recovered. In October the right axillary and subclavian could be felt as a hard pulseless cord, and there was no pulse in any of the vessels of the limb, which was cold and slightly wasted. There was no pulsation in the right temporal, but the carotid seemed to be healthy. A somewhat similar case occurring in a female, aged 35, was recorded by W. B. Hadden in 1884.

In a later case recorded by Gould, a man, aged 43, was attacked with acute mania after influenza. Eleven days after the onset of the maniacal symptoms the patient complained of pain extending from the right knee to the foot, and two days later the foot became cold and blue. Gangrene rapidly followed and the same series of changes occurred in the left limb, so that on the tenth day after the first complaint of pain was made, both feet were gangrenous to above the malleoli. The gangrene was dry at the tips of the toes, but in other parts the dead tissues remained soft. Pulsation was felt in the left popliteal artery, but on the right side the vessel was "a hard pulseless cord." Amputation was successfully performed through both knee-joints (see Vol. I., p. 815). In both the amputated limbs there was "a wide-spread endarteritis and endophlebitis affecting both large and small vessels." The intima of the affected vessels was irregularly thickened by an overgrowth of fibroid tissue and a round-celled infiltration. This case was remarkable in the symmetrical character of the gangrene and in its rapid onset.

The pathology and causes of this rare affection are still uncertain. It commonly occurs about middle life, Gould's first case being the youngest recorded. The disease described by Von Winiwarter under the name of *endarteritis proliferans* is probably of the same nature. He states that it occurs

in persons apparently healthy in other respects, and gives rise to spontaneous gangrene, usually of the foot. In one case in which the vessels were examined after amputation of the limb, the obliteration was found to be the result of a great proliferation of the endothelium, with narrowing of the lumen of the vessel, the final obliteration being brought about by thrombosis. New vessels were found penetrating from the outer coat into the proliferating endothelium, which with the thrombus was found in the older parts to be undergoing changes similar to those already described as occurring in closure of an artery after ligature. Billroth states that the disease is preceded by feebleness of circulation, and obscure pain, often lasting for months or years. There is no definite treatment for these cases.

#### PRIMARY DEGENERATIONS OF ARTERIES.

**Fatty Degeneration.**—Fatty degeneration, except as a part of chronic endarteritis, is not a particularly frequent or important change in arteries. In the aorta, even in young subjects, yellow patches of small size and irregular form, and very slightly if at all elevated above the normal surface of the intima, are common. If one of these be peeled off and examined microscopically it will be found to present stellate patches of fat granules in the most superficial layers of the intima, immediately beneath the endothelium. These are the result of fatty degeneration of the branched cells that are normally present in this part. The affection seems of no importance, and its cause is not known.

In later life, fatty degeneration affecting the intima more deeply is sometimes met with unaccompanied by any of the signs of atheroma. The degeneration may extend to the endothelium, which then disintegrates and is cast off, leaving a rough surface exposed. This condition has been described as *fatty erosion*. It is most common in the arch of the aorta. Through such a surface the blood may force its way into the middle coat, and thus give rise to the condition to be subsequently described as "*dissecting aneurism*."

Fatty degeneration of the muscle-cells of the middle coat is described by Ziegler as an occasional antecedent of the annular form of calcification.

Fatty granules are not uncommonly found in old age in the external coats of the smaller arteries, but they are of no pathological importance.

**Albumenoid or Amyloid Degeneration.**—This has already been considered in Vol. I., p. 251. The degeneration appears usually, if not always, to begin in the blood-vessels of the affected part, especially in the muscle-cells of the middle coat of the small arteries. In the larger arteries the inner coat may be affected. Some interference with the blood-supply of the part is caused in this way, and this may serve to explain the frequency with which fatty changes are found in association with albumenoid disease.

**Calcification or Calcareous Degeneration.**—We have already seen that the calcareous plates so common in the aorta and its primary branches are the result of the calcification of the products of chronic endarteritis. In the smaller arteries, principally in those of the third and fourth magnitudes, as the popliteal, the tibials, the brachial, radial and ulnar, primary calcification is commonly met with. It commences by the deposit of lime salts, in a granular form, arranged in lines running transversely to the axis of the vessel; these lines gradually increase in breadth until they coalesce laterally, the

intervening spaces being filled up and the vessel converted into a rigid tube. In the early stages while the calcareous matter is arranged so as to form lines round the vessel, the condition is termed *annular calcification* (Fig. 440). When these lines have coalesced it is often called *tubular calcification* (Fig. 441).

When this process has reached its highest stage, if the artery be removed from the body and drawn through the fingers, a small rigid tube, composed of the calcified middle coat still lined by the inner coat, can be squeezed out, leaving the external coat apparently healthy. In fact, the toughness of the external coat is so little impaired that such a vessel can be tied, and even twisted, almost as safely as a healthy artery. Annular and tubular calcifica-

Fig. 440.—Annular Calcification.

Fig. 441.—Annular Calcification, becoming Tubular.

tions are almost invariably associated with chronic endarteritis and its secondary degenerations in the larger vessels; and in the intermediate arteries, such as the axillary or popliteal, and sometimes even as low as the tibials, both conditions are observed side by side.

The existence of this degenerative change is usually recognized without difficulty during life in any artery that can be examined with the finger. The vessel feels hard and less compressible than natural. Its longitudinal elasticity is lessened, so that it is thrown into a wavy line when relaxed longitudinally by flexion of the limb.

The morbid condition consists essentially of a deposit of lime salts in the muscular fibre cells of the middle coat. We thus meet with it only in those vessels in which the muscular tissue is well developed. In the larger arteries

the muscular cells are so scanty and so far concealed by the elastic tissue that if this change does occur in them it is difficult to recognize. The inner coat in the larger vessels usually shows the ordinary signs of chronic endarteritis. In the smaller it may at first be healthy, but later on calcareous plates may form in it. It has been pointed out by Bizot that the symmetry of the arrangement of these morbid appearances in the corresponding vessels on opposite sides of the body is remarkable, the arteries of one limb often being the exact counterpart in this respect of those of the other.

The causes of calcification of the muscular fibre cells of the middle coat are unknown beyond that it is always a senile change.

The effects of annular calcification are to render the vessel a rigid tube no longer capable of regulating the flow of blood to the parts it supplies. At the same time its calibre is always diminished, and the nutrition of the parts beyond is seriously impaired. Thus in the limbs we have all the signs of defective circulation, coldness of the feet, cramps and spasms of the muscles; whilst, in organs, softening of tissue, fatty degeneration, and other evidences of want of a proper supply of blood are observed. Spontaneous aneurisms rarely result from this change, the coats of the arteries being more resisting than natural; moreover, primary calcification is met with in the vessels below the axilla and knee, and spontaneous aneurisms beyond those points are amongst the curiosities of surgery. Thrombosis is occasionally met with, but is not common, as the endothelial lining is affected only in extreme cases and late in the disease. The lodgment of a small fibrinous embolus carried from atheromatous arteries above is an occasional occurrence, and is very likely to cause gangrene even when only one vessel is blocked, as the collateral arteries are no longer capable of enlarging to carry on circulation. Occlusion of the calcified arteries by thrombosis or embolism is the common cause of the dry form of senile gangrene. The moist form arises from inflammation taking place in tissues the vitality of which has been greatly lowered in consequence of the diminished supply of blood through the narrowed vessels.

**Ossification of Arteries.**—The formation of true bone in the coats of an artery is an extremely rare occurrence. A specimen of this kind was exhibited at the Pathological Society of London, by H. G. Howse, in 1877. The patient was a man aged 36, who was run over by a cart, the wheel passing over his shoulder. The axillary artery was ruptured, and death occurred as a result of the accident about a month afterwards. A small plate of cancellous bone was found in the injured vessel, apparently developed in the middle and outer coats. Its greatest thickness was about a quarter of an inch.

**EFFECTS OF DISEASES OF THE ARTERIES.**—The various effects of diseases of the arteries have already been mentioned with the affections to which they are due, but it may lead to a clearer comprehension of the subject if they are again referred to, as the same effect may result from more than one cause. The most important effects of arterial disease are Ulceration of the Coats of the Artery; Spontaneous Rupture; Contraction or Occlusion of the Vessel; and, lastly, Dilatation into some of the various forms of Aneurism.

**Ulceration of Arteries.**—Loss of substance in the inner coat results from superficial fatty degeneration (p. 95), and from softening of an atheromatous patch (p. 89). Neither of these processes is a true ulceration. Genuine ulceration of the inner coat is in reality scarcely ever met with. When true

ulceration of an artery takes place, it is the result of causes acting from without, attacking first the external coat, as in the case of a sloughing sore opening a main artery, or the pressure of a sequestrum in the popliteal space against the vessel.

**Spontaneous Rupture** of an artery is rare, and never happens without previous disease of its coats. Experiments made by Peacock, which I have repeated, and the accuracy of which I can fully confirm, prove that a healthy artery will sustain a very great pressure from water injected into it, without its walls giving way. But if these have been softened or weakened by disease, they may be unable to resist even the ordinary impulse of the blood: and if this be driven on by any unusually forcible action of the heart, as under the influence of sudden violent strain or exertion, they may give way. This occurrence would be much more frequent than it is in atheromatous and calcareous patches, were it not for the inflammatory consolidation of the external coat of the vessel supplying that resistance which has been lost by the softening or destruction of the internal and middle tunics. Hence this rupture is most frequent in those vessels the outer coat of which is the thinnest, and in which, consequently, it can least supply the place of the others, as in the arteries of the brain and in the intrapericardial portion of the aorta. The liability to rupture of a diseased artery by the distensile force of the blood impelled into it is increased by the existence of an obstacle to the free flow of the blood out of its terminal branches in consequence of a congested, infiltrated, or chronically thickened state of the organ or part supplied by it.

**Contraction and Occlusion** of arteries are by no means rare sequences of lesions of these vessels. Narrowing of an artery may take place in various ways: the orifice of a branch leaving an atheromatous trunk is often narrowed by the formation of a ring-shaped thickening of the inner coat (p. 93), and the calibre is diminished in calcification of the middle coat (p. 96), syphilitic arteritis (Vol. I., p. 1132), and endarteritis proliferans (p. 23). Causes acting from without, as pressure, or contraction of chronic inflammatory or cicatricial tissue in the immediate neighbourhood of the artery, lead to a narrowing of its lumen. In this way the axillary, the iliac, and even the aorta, have been occluded. Tiedemann records from various sources no fewer than eight cases in which the abdominal aorta was completely closed, in all of which so full and efficient a collateral circulation had been set up that the vitality of the lower part of the body was perfectly maintained, and in most the morbid state was not suspected during life. Besides these cases, he states that there are on record twelve instances of great narrowing of the aorta, at that point where the ductus arteriosus is implanted into it in foetal life. These would appear in some way to be connected with the closure of the duct: as in every case the indentation was greatest on the convex part of the aorta, which had been drawn in towards the mouth of the duct.

The final obliteration of a diseased artery is most commonly the result of *thrombosis*. Thrombosis takes place in arteries under much the same conditions as in the veins. Whenever the normal endothelial lining of the vessel is lost or its "physiological integrity" impaired by degenerative changes, the blood tends to coagulate upon the diseased surface. The rapidity of the arterial flow, by preventing the adhesion of the white corpuscles, counteracts this tendency to a certain extent, but when the blood-stream becomes slackened either by great dilatation of a large trunk, or by narrowing of the orifice of a branch or feeble-

ness of the heart's action, a deposit of fibrin very readily takes place. An artery of the second or third magnitude may thus be obliterated. When a thrombus has formed in a branch it may extend by fresh deposit into the main trunk, and form a mass of fibrin projecting into its lumen (Fig. 442). Thrombosis

Fig. 442.—Thrombosis of two of the chief branches of the abdominal aorta; projection of the thrombus into the main trunk.

Fig. 443.—Embolism of the axillary artery with thrombosis of the brachial for some distance below the embolus. 1. Subclavian; 2. Axillary artery; 3. Subscapular and post. circumflex arteries; 4. Brachial.

of the diseased artery is probably in a considerable number of cases the determining cause of dry gangrene in old people.

Complete obliteration of an artery is in many cases the result of *embolism*. The embolus is usually composed of a mass of fibrin which has been deposited on some diseased part of the larger vessels, and subsequently washed away by the blood-stream and lodged in some part at which the trunk suddenly narrows when bifurcating or giving off a large trunk. The source of the embolism may be the vegetations formed upon the valves of the heart in acute rheumatism or ulcerative endocarditis, the fibrin deposited in a pouch of a dilated aorta, or on a projecting calcareous plate, or a fragment of a clot projecting

into the main trunk from a thrombosed branch, as in Fig. 442. The effects produced vary with the nature of the embolus and its size. When derived from the vegetations on the valves in ulcerative endocarditis it may give rise to inflammation and softening of the coat of the artery at the point at which it lodges (see Embolic Arteritis, p. 86); more commonly it leads merely to obliteration of the artery by the ordinary processes already described. If it lodge in a small artery in a part in which the anastomosing circulation is free, it produces no effect beyond the permanent closure of the vessel; if it lodge in a terminal artery, as in one of the abdominal viscera, it gives rise to the formation of a hæmorrhagic infarct (Vol. I., p. 981), followed by the subsequent degeneration and shrinking of the affected area. These old infarcts, forming wedged-shaped buff-coloured patches of considerable toughness, are commonly met with in the spleen and kidneys in cases of advanced atheroma or fusiform aneurism of the aorta. When the embolus is large and lodges in a main trunk, as in the popliteal at its bifurcation, or in the axillary, spontaneous gangrene may result. This is the most common source of gangrene in young people, and is probably the immediate cause of a certain proportion of cases of senile gangrene, the embolus in the latter case being derived from the diseased surface of an atheromatous aorta. The case from which the accompanying drawing (Fig. 443) was taken was that of a woman 56 years of age admitted for spontaneous gangrene of the left arm; the embolus lodged in the axillary artery had caused gangrene of the limb. The figure illustrates also the thrombosis of the vessel below the part at which the embolus has lodged, which frequently aids in the production of gangrene.

Gradual narrowing of an artery, ending perhaps in complete obliteration, causes few or no symptoms when the area affected is limited in extent and the collateral circulation is sufficiently active to keep up the supply of blood to the parts beyond the obstruction. The gradual narrowing of a considerable extent of the main vessels of the limb, such as is seen frequently from calcareous degeneration of the tibial arteries, gives rise to more or less definite effects, such as cold feet, cramps, numbness, and weakness of the legs. Such symptoms are often the premonitory signs of gangrene (see Vol. I., p. 904), and are an indication that care must be taken to keep the parts warm by appropriate clothing and to avoid any injury. The symptoms of embolism of a large trunk have already been described (Vol. I., p. 906).

## CHAPTER XLIII.

## ANEURISM.

**An Aneurism** is a tumour, resulting from dilatation of the whole or a portion of the coats of an artery caused by the pressure of the contained blood, and communicating with the interior of the vessel. Traumatic aneurisms have already been described (Vol. I., p. 464). Spontaneous aneurisms are alone considered in the present chapter.

**CAUSES.**—The causes of aneurism are divisible into predisposing and exciting. Aneurism is **Predisposed** to by any affection of the arterial coats that lessens their elasticity and resisting power. When an artery has undergone any of the degenerative or chronic inflammatory changes described in the last chapter, it becomes less able to recover during the diastole from the distension occurring during the systolic impulse, and thus either complete or partial dilatation takes place. Calcification prevents rather than favours dilatation of the artery, by hardening the coats and converting them into rigid inelastic tubes ; but atheroma softens them, and causes yielding of that portion of the vessel affected by it. I have frequently observed that the whole of an artery might be healthy except at one part, where there was an atheromatous patch, and there the vessel was dilated ; or that the whole of its coats might be calcified, except at one spot, where softening had taken place, and where consequently they had yielded under the outward pressure of the contained blood.

As aneurism, therefore, may be looked upon as one of the sequences of chronic endarteritis, the predisposing causes of the one condition must necessarily be the same as those of the other. Hence we find that age, gout, and syphilis influence the occurrence of the aneurismal disease by laying its foundations in the development of atheroma.

**Age.**—Aneurisms are most frequently met with during the middle period of life—at that age, indeed, when the arteries have already commenced to lose their elasticity, in consequence of degenerative changes, whilst, at the same time, the heart has not lost any of its force, or the general muscular system its vigour. This disease is excessively rare before puberty, yet is occasionally met with at early periods of life : thus Syme mentions a case of popliteal aneurism in a boy of seven, Hodgson had a preparation of a carotid aneurism in a girl of ten, and Schmidt records a case of spontaneous aneurism of the radial artery in an infant eight weeks old. R. W. Parker, in a most valuable paper on aneurisms in young subjects read before the Medico-Chirurgical Society in 1863, states that, after a careful search in medical literature, he has found only fifteen cases of spontaneous aneurism recorded as occurring under the age of twenty, including a case of his own of inguinal aneurism in a boy aged twelve years and eight months. In eight of the fifteen cases there was disease of the valves of the heart, in five the state of the heart was not recorded, and in two only was it stated to be healthy.

**A forcible, and occasionally greatly increased action of the heart,** is often the immediate cause of the dilatation of the vessels and the production of aneurism. Hence we find that this disease is especially common in those individuals who are called upon to make sudden, violent, and intermittent exertions; as, for instance, in men who habitually lead somewhat sedentary lives, but occasionally change their habits suddenly and indulge in active sports, which they might without risk have practised in early life, but which cannot be taken up with impunity at an age when the arteries are unable to bear the same strain upon their coats as heretofore. I agree with Porter in thinking that continuous, steady, laborious employments do not predispose to aneurism, as this disease is seldom met with amongst those of the working class who labour hard and uninterruptedly; while it is common in soldiers, sailors, and members of the wealthier classes in society. As violent muscular exertion predisposes to this disease, we should necessarily expect to meet with it more frequently among men than in women: and accordingly Crisp finds that, of 551 cases of aneurism of all kinds, more than seven-eighths occurred in men. It is important, however, to observe that different kinds of aneurism occur with varying degrees of frequency in the *sexes*: thus, carotid aneurism is met with about as often in women as in men, whilst the other external aneurisms occur in the proportion of thirteen cases in males to one in females. It is remarkable, however, that in the dissecting aneurism the proportions are reversed, for twice as many occur in women as in men.

**Climate.**—Aneurism is far more frequent in cold than in hot countries. It is not, however, the geographical position or the meteorological condition of a country but rather the habits of the people that regulate its prevalence. It is to the more energetic and active habits of the northern nations that we must look for an explanation of its greater prevalence amongst them. If we may judge of the prevalence of aneurism in a country by the number of published reports of cases, I should say that it is more common in Great Britain and Ireland than elsewhere; indeed, Roux states that it is less frequent in France than in England. In America it is also of frequent occurrence, but in the East Indies it is comparatively rare.

All those **Constitutional Conditions** which predispose to or cause chronic endarteritis or atheroma necessarily act as predisposing causes of aneurism. (See Causes of Atheroma, p. 90.) Syphilis is commonly said to tend specially to the production of aneurism, but I am not aware that we are in possession of any definite facts proving this. The increased arterial tension accompanying the chronic interstitial nephritis and general arterio-capillary fibrosis of chronic gout undoubtedly acts as a powerful predisposing cause of aneurism. Phthisis is antagonistic to aneurism on account of the feebleness of the heart's action and the low arterial tension; moreover, violent muscular exertion is seldom undertaken by those labouring under it.

**Embolism** is probably in the great majority of cases the cause of spontaneous aneurisms of the smaller arteries, as the radial, ulnar or tibials, and especially of aneurisms occurring in young subjects. There is no reason to believe that a simple embolus ever causes aneurism, for the increased pressure resulting from the resistance is felt throughout the general circulation, and not merely in the vessel immediately above the obstruction. The essential element in the production of an aneurism by embolism is the softening of the coats of the vessel consequent upon the irritating nature of the material of which the

embolus is composed. Such an irritating embolus is commonly derived from a diseased valve of the heart in the case of ulcerative endocarditis. The subject of embolic arteritis has already been considered (see p. 86).

Any **obstacle to the free flow of blood** through an organ or the capillaries of a part causes an elevation of the arterial tension, but this is not greater in the vessel leading to the part in which the obstruction is seated than in the arterial system generally. Thus it has been shown experimentally that if the femoral artery be tied the increased arterial tension resulting from the obstruction thus introduced into the circulation is the same in the artery immediately above the ligature and in the carotid. Chivers's theory that aneurisms of the abdominal arteries are frequently due to obstruction in the abdominal organs is probably devoid of foundation.

The only **Exciting or Direct Occasioning Causes** of aneurism are blows, violent strains, and wounds of an artery. When an atheromatous artery is concussed by a *blow*, the lining membrane covering the softened patch may be ruptured, the *débris* being poured out into the interior of the vessel; and the external coat, with a portion of the middle adherent to it, having alone to bear the blood-pressure before it has been fully consolidated by chronic inflammation and the formation of new fibroid tissue, the foundation of an aneurism may readily be laid. In very forcible muscular efforts, it is easy to understand how an already weakened portion of the vessel may become dilated by the increased arterial tension; occasionally even the vessel may be completely torn across by a violent strain. *Wounds* implicating arteries are common causes of those various forms of aneurism that have already been discussed in considering Injuries of Arteries (Vol. I., p. 474).

**CLASSIFICATION.**—Aneurisms may be classified as follows :—

1. FUSIFORM.

2. SACCULATED.— { *a.* True.  
                          { *b.* False.

3. DISSECTING.

1. **Fusiform or Tubular Aneurism.**—This is a dilatation of an artery, affecting the whole circumference of the vessel. The fusiform aneurism is not a mere dilatation of the vessel, for there are elongation, thickening, and degeneration of its walls as well. The elongation of the artery in the fusiform aneurism is as marked as its dilatation. Thus the arch of the aorta may be increased in length by some inches, with a considerable space between the origins of the innominate, the carotid, and the subclavian, at the same time that its walls are greatly thickened, nodulated, and rugged. Sometimes several fusiform aneurisms are met with in the same vessel, with healthy portions of the artery between them. From these dilatations, sacculated aneurisms not uncommonly spring.

On examining the structure of a fusiform aneurism, it will be found that the thickness of the wall is maintained by growth from the inner and outer coats, the middle coat being stretched and atrophied in proportion to the size of the aneurism. The inner coat presents the changes already described as resulting from endarteritis: it is stiff, rugged, and tuberculated from the formation of atheromatous patches, and frequently calcareous plates are scattered over its surface. The outer coat is thickened and composed of dense fibroid tissue. Microscopic examination shows that the middle coat is thinned in proportion to the degree of dilatation. If the aneurism is of any consider-

able size, gaps are found here and there in which the middle coat is wanting, the diseased inner coat coming into direct contact with the thickened outer coat. No coagula are found in the dilatation, but a few filamentary shreds of fibrin are occasionally seen attached to the inner wall. Fusiform aneurisms are most common in the arch of the aorta (Fig. 444), the iliacs, the femorals and occasionally the axillaries; in fact, in those vessels in which the yellow elastic tissue of the middle coat is largely developed. They are rare in arteries smaller

than the femoral, the basilar artery of the brain, however, being an exception.

Fig. 444.—Large Fusiform Aneurism of Ascending Aorta bursting into Pericardium.

A fusiform aneurism, especially of the arch of the aorta, may attain a great size, and exercise injurious pressure on contiguous parts, producing great distress and danger to life. It increases slowly, and may be compatible with life for many years; but it usually destroys the patient at last, and may occasion death in several ways. Thus, if it be situated in the aorta, death may take place from syncope. This may be caused by the failure of the inelastic aorta to fill the coronary arteries during the diastole of the heart, or from imperfect supply of blood to the brain. Then, again, death may result from pressure on important parts, as on the bronchi or the oesophagus. When, however, a tubular aneurism of the arch of the aorta occupies the intrapericardial portion of the vessel, it not unfrequently happens that,

owing to the absence of a sheath in this situation, the artery may rupture. In other situations it most commonly remains quiescent, being a source of discomfort, but not of death, until a sacculated aneurism springs from its side, which then becomes the more formidable affection.

**2. Sacculated Aneurism.**—By a sacculated aneurism is meant a tumour springing from the side of an artery or of a fusiform aneurism, with the interior of which it communicates by a narrow aperture, called the mouth of the sac (Fig. 446). It is generally divided into the *True* and *False* varieties.

**True Sacculated Aneurism.**—In this variety the blood is contained within a sac continuous with the coats of the artery and distinct from the surrounding tissues. In all parts of the sac one or more of the coats of the arterial wall are still recognizable. It is only in the earliest stages of the formation of a sacculated aneurism that all the coats of the artery can be traced in the sac wall. Thus, we occasionally find, as Peacock pointed out, small digital pouches springing from the walls of some of the larger arteries, through the whole of which the external, middle, and internal coats can be demonstrated by maceration to exist; and in those aneurisms which are formed by the dilatation of a comparatively large portion of the arterial wall, the same condition may for a time be found, as I have ascertained by careful dissection. As the sac of the aneurism increases in size the thickness of its wall is maintained, and indeed usually increased, by an overgrowth of the outer coat and

in a lesser degree of the inner coat. At first, as we have seen, all the coats are recognizable in the sac, but soon the middle coat is found only in patches with wide gaps between them. With the further increase in the size of the sac all traces of the middle, and usually of the internal, coat are lost, so that the wall is formed of dense fibroid tissue, chiefly derived from the outer coat of the artery. This is strengthened by its adhesion to the neighbouring parts, which become fused into its structure as a consequence of the chronic inflammatory process set up round the aneurism from the pressure it exerts upon the surrounding structures.

In the majority of cases, however, a sacculated aneurism arises in an atheromatous patch in which the internal coat and the innermost layers of the middle coat have already been destroyed. In such cases the sac is from

Fig. 445.—Sacculated Aneurism of Ascending Aorta. Death by Pressure.

Fig. 446.—Upper part of Descending Aorta laid open, showing the mouth of the sac of an Aneurism. The inner coat round the opening is irregular from patches of atheroma and masses of fibrin.

the first chiefly formed by the thickened outer coat, and only shows remains of the middle coat in the earliest stages and near the mouth of the sac.

The formation of an aneurism by the hernial protrusion of the internal and middle coats through an ulcerated aperture in the external coat has been described ; but, though there is a preparation in the Museum of the College of Surgeons that is supposed to illustrate this fact, I doubt the existence of such a form of the disease, and after careful examination think that the preparation in question represents rather an artificial dissection than a true rupture of this dense and resisting structure.

**False Sacculated Aneurism.**—In this variety all the coats of the artery are absent in some part at least of the sac of the aneurism, which is here formed only by the condensed connective tissue of the structures in which the tumour is situated. This variety results from the gradual yielding of the sac of a true sacculated aneurism ; the blood, although effused beyond this, is still confined in a sac of condensed areolar tissue formed by that of the structures

into which the blood has been effused, matted together with coagulum and inflammatory exudation. It occasionally happens that a more or less sudden rupture of the sac occurs, followed by widespread extravasation of blood into the tissues of the part. To such a condition the name "diffused aneurism" is sometimes applied.

3. **Dissecting Aneurism** is a form in which the sac is situated in the wall of the artery between its coats. It originates in consequence of the internal coat of the vessel becoming eroded, and giving way before any of that matting together of the tissues around the patch has taken place, which prevents the

blood from being forced between the different tunics of the artery. The rupture, although originating in the internal coat, always extends between the layers of the middle one, splitting this up into two laminae, and in some cases it also separates the middle from the external coat of the vessel (Fig. 447). On examining the artery in a case of dissecting aneurism, its coats will always be found to be easily separable from one another, and to be very lacerable. For the production of this disease two conditions are necessary: 1. That there be atheromatous disease of the artery, destroying a portion of the internal and of the innermost layers of the middle coat; and 2. That there be a general softening of the tissue of the middle coat, with want of cohesion between the different tunics of the artery.

In a dissecting aneurism the blood may often extend to a very considerable distance between the layers of the middle coat. Thus it may reach from the arch of the aorta to the iliacs, or from the same part to the bifurcation of the carotids. The disease occurs only in the aorta, and its principal branches, in

Fig. 447.—Dissecting Aneurism of Arch of Aorta. The inner and middle coats (a) have been ruptured transversely about an inch beyond the semilunar valves. These coats have been extensively separated by the blood from the outer coat (b).

which yellow elastic tissue is abundant in the middle coat.

Dissecting aneurisms arrange themselves into *three distinct classes*. 1. In one class, the blood, after having passed several inches through the substance of the middle coat, bursts through the external coat, and becomes effused into the areolar tissue outside the vessel, or into the neighbouring cavities. In these cases, which constitute the most common variety of the disease, death usually occurs rapidly, the patient feeling intense pain along the line of rupture and falling into a state of syncope. 2. The external coat may resist the impulse of the blood, which consequently continues to pass between the layers of the middle coat until it meets a softened and atheromatous patch, and then again bursts into the lumen of the artery. In this form the patient may live for years after the rupture; the new channel that the blood has

taken becoming lined with a dense smooth membrane resembling closely the interior of the artery, from which, however, it is separated by a kind of septum. This condition has occasionally been erroneously described as a double aorta. 3. The blood may find its way between the laminæ of the middle coat, but does not escape farther by rupture of the external, or by the giving way of the lining membrane of the vessel. A sac is consequently formed in the substance of the middle coat, which may become chronic, but which will at last rupture externally.

**Structure of a Sacculated Aneurism.**—An aneurismal sac may vary in size, from a tumour not larger than a cherry to a growth of the magnitude of a cocoa-nut. The mouth, which is oval or round in shape, varies greatly in size, being always very small in proportion to the sac. Usually the interior of an aneurismal sac contains a quantity of colourless fibrin, arranged in concentric laminæ of but moderate thickness; these laminæ of fibrin are of a pale-buff colour, dry, and somewhat brittle where they are most closely applied to the wall of the sac; the more external were first deposited, and occasionally are found to have undergone a kind of fatty degeneration; as we approach the interior of the vessel, they become softer and more coloured, and at last, in the central portions, dark masses of coagulum are often met with.

This colourless laminated fibrin was termed by Broca the *active* clot, as it is deposited only when the blood is in motion in the sac of the aneurism. It is formed in the same way as a colourless thrombus in a diseased vein (see p. 54), the first step in the process being the adhesion of a layer of white corpuscles to the diseased surface. These disintegrate, and thus determine the formation of a layer of fibrin. The microscopic examination of recent laminated clot shows the presence of numerous white corpuscles which have not undergone disintegration between the layers of fibrin. It is probable that these are of a different nature from those which take part in the process of coagulation. In the older layers of clot no corpuscles are recognizable, but much fatty and granular matter is always found, which may have resulted from their disintegration. The part played by the adhesion of the corpuscles in the deposit of laminated fibrin explains the influence of retardation of the blood-stream on its formation. In fusiform aneurisms in which the flow of blood is rapid throughout the dilated vessel, adhesion takes place with difficulty, and no clot is usually formed, while in sacculated aneurisms in which the movement of the blood is necessarily much slower, laminated fibrin is always abundantly deposited. It will afterwards be seen that those modes of treatment by which the flow of blood through the sac is retarded, exert the most powerful influence in determining the deposit of layers of clot. The colour of the clot varies in different cases: the more rapid the flow of blood, the fewer red corpuscles will be entangled in the coagulum; the slower it is the darker the clot will be. Complete arrest of the circulation leads to the formation of an ordinary dark blood-clot, exactly like that produced when blood, withdrawn from the body, is allowed to coagulate. Clot of this kind is always found *post mortem* in the middle of the sac of the aneurism, and is then formed probably immediately before or after death. Those modes of treatment which completely arrest the flow of blood into the sac cause the formation of a similar coagulum. It is the *passive* clot of Broca.

The layers of fibrin in the laminated clot are more or less concentrically arranged, but no single lamina reaches over the whole sac. The older layers

bear evidence of having been formed when the cavity was smaller and subsequently flattened out against the enlarged walls of the sac (Fig. 448). The deposit of laminated fibrin exerts a powerful influence in preventing the too rapid increase of the tumour. Another great purpose it serves is to lessen the capacity of the sac, and thus to diminish the pressure on surrounding parts, the distending force of the aneurism being proportional to the area of the sac as well as to the force with which the blood is driven into it. In those cases in which the laminated fibrin is small in quantity or altogether deficient, the aneurismal tumour rapidly increases with a forcible pulsation that is not met with in other circumstances. The dark coagulum, or passive clot of

Fig. 448.—Large Aneurism of Ascending Aorta, projecting against (and protruding outwards) the ribs. Layers of Laminated Fibrin arranged in the direction of the Current of the Blood.

Broca, is a less efficient support to the wall of an aneurism than the colourless or active clot. It is much softer, and at first contains a large amount of serum; this gradually squeezes out as the clot contracts, which thus becomes considerably diminished in bulk. If the clot completely fills the sac this contraction may possibly be followed by the re-establishment of a cavity, but the experience of some of the modern modes of treatment shows that this is not very likely to occur, the contraction of the clot being accompanied by a corresponding diminution in the size of the sac, chiefly due to the pressure of the surrounding structures. The clot further diminishes from the disintegration of the

red corpuscles which form the chief part of its bulk. As this takes place it becomes decolorized, and thus, if the sac is only partly filled by a dark clot, this becomes flattened out and finally forms a layer indistinguishable from the laminae of colourless fibrin.

**Pressure-Effects.**—As an aneurism enlarges, it exerts injurious and often fatal effects by its pressure upon contiguous parts. These pressure-effects deserve attentive study, as they constitute an important element in the diagnosis of aneurism. The pressure on the surrounding parts increases with the size of the sac. Dr. Stone thus describes the influence of increase in size on pressure: "The hydrostatic force rises rapidly as the sac enlarges; in fact, in a modified geometrical ratio as against a simple arithmetical increase of the heart's action. We are thus from the first losing ground, and the malady is gaining on us according to some simple function of the fundamental law of equality of pressure in all directions." Supposing the aneurism to have a diameter of 3 inches, its internal surface will be 28.26 square inches, which, if the blood-pressure be reckoned at 3 lbs. to the square inch, gives a total pressure in the sac of 84.81 lbs. If the sac enlarges until its diameter reaches 4 inches, the internal surface will be 50.26 square inches and the pressure 150.78 lbs. An aortic aneurism presenting on the surface as a tumour 3 inches in diameter would lift a quarter of a hundredweight.

One of the most common effects of aneurism is œdema of the limb or part,

owing to the pressure of the tumour on the *venous trunks* in its vicinity. The consequent obstruction to the venous circulation may also give rise to a distended or varicose condition of the subcutaneous vessels, and in some instances it may even go on to the production of gangrene. The pressure of the sac, also, on neighbouring *arteries*, or even on the upper part of the very vessel from which it springs, and its interference with the general capillary circulation of a part, are commonly associated with compression of the veins, and may considerably increase the ill consequences resulting from it. The pressure upon a neighbouring artery may go on to perforation of the vessel by the sac, and so a communication between the two may be set up: thus aneurism of the aorta has been known to perforate and communicate with the pulmonary artery. Pressure upon neighbouring *nerves* may give rise either to great pain in the part supplied by them, or to disturbance of their function; the nerves themselves becoming in some cases flattened out, and ribbon-like (Fig. 449), and in other instances considerably elongated. The pain in the nerves is often one of the earliest signs of the existence of an aneurism. The pain is usually of two kinds: it is either lancinating and radiating along the course of the nerve that is compressed; or, when the tumour presses severely upon neighbouring parts and *tissues*, more especially if it give rise to erosion of the bones (as in Fig. 448), an aching, burning, tearing, or boring sensation is often experienced in the part subjected to the pressure. In other cases, again, important modifications in the function of parts take place, in consequence of the pressure that is exercised upon their *nerves*, as in the affection of the larynx caused by pressure on the recurrent laryngeal nerve. On the *bones* an aneurism may produce very important effects by its pressure, often deeply eroding the osseous tissue. If the bone be a flat one, as the sternum, the aneurism may perforate it by making as smooth and round a hole in it as if this had been worked by the trephine. *Glandular organs and their ducts* in the neighbourhood of aneurisms suffer the most injurious effects from the pressure of these tumours, their functions being arrested and the passage of their secretions interfered with; so, also, by the pressure exercised on the *trachea* and *œsophagus*, respiration and deglutition may be seriously impeded.

**Number.**—Aneurisms, though usually single, are not very unfrequently multiple. There may be more than one in the same limb: thus the iliac and femoral arteries on the same side may be affected. In other cases, corresponding arteries are affected: thus the two popliteals are occasionally the seat of this disease, and an external aneurism may co-exist with one in the thorax or abdomen. Numerous aneurismal tumours are at times met with in the same person: thus, Pelletan records a case in which no fewer than sixty-five were observed.

**Duration.**—The duration of an aneurism varies very greatly. In young full-blooded persons it often makes progress with great rapidity; whereas in elderly people of feeble constitution, in whom it is accompanied by more or less feebleness of the heart's action, it may assume a very chronic form. Thus,

Fig. 449. — Flattening of Posterior Tibial Nerve by pressure of an Aneurism of the Calf.

Hodgson relates a case of aneurism of the femoral artery of twenty years' duration. High arterial tension, as in cases of chronic Bright's disease, with hypertrophy of the left ventricle, is undoubtedly favourable to progressive increase of an aneurism. Much also will depend on the situation of the aneurism, the size of the mouth of the sac, and the relation of the sac to the impulse of the blood into it; the larger and more direct the mouth of the tumour, the more readily will the blood be projected into it at each impulse of the heart, and the more quickly will it expand.

**Symptoms.**—The symptoms of an aneurism are of two kinds: 1. Those that are peculiar to this disease; and 2. Those that are simply dependent on the presence of the tumour occasioned by the enlarging sac. The peculiar or pathognomonic signs are those that are dependent on the communication of the sac with the artery, and which are ascertained by the manual and auscultatory examination of the tumour; those that are dependent on the mere size of the growth are the pressure-effects. It is, of course, only in external aneurisms that those signs which are ascertainable on manual examination of the tumour can usually be recognized. In internal aneurisms, in the majority of cases, the auscultatory signs and the pressure-effects afford the best indications of the presence and nature of the tumour; though, when this approaches the surface, much information can be gained by palpation.

**Symptoms of External Circumscribed Aneurism.**—The tumour is usually round or oval, distinctly circumscribed, and in close connexion with some large artery. It is at first somewhat compressible, but afterwards becomes more and more solid as fibrin is deposited in it. The most marked sign is, perhaps, the *pulsation* that is felt in it from the very first. This is of a distensible, eccentric, and expanding character, separating the hands when laid upon each side of the tumour, by a distinct impulse from within. The pulsation is most forcible in an aneurism in which there is but little laminated fibrin; and as this increases in quantity the pulsation gradually loses its tense expanding character, being converted into a dead *thud*, and in some cases ceasing entirely. When pulsation is obscure, the compression of the artery below the sac will cause it to become more distinct, or it may be increased in distinctness by elevating the limb or part affected. When the artery above the sac is compressed, the flow of blood into the tumour is necessarily arrested, pulsation ceases, the tumour diminishes, and its size may be still further reduced by gentle pressure, which squeezes out a considerable quantity of its more fluid contents. If the hands be then laid upon each side of the tumour, and the pressure be suddenly taken off the artery, the blood will be found to rush into and distend the sac by a sudden stroke, separating the hands from each other. This may be looked upon as one of the most characteristic signs of aneurism.

The *bruit* or *sound* emitted by the blood in its passage through an aneurismal sac was first noticed by Ambroise Paré. It varies much in character, being usually loud, rasping or sawing; it is loudest and roughest in tubular aneurisms. Occasionally the bruit is double, and if so, it clearly indicates the sacculated nature of the aneurism. It is possible, however, that when great aortic regurgitation is present, the backward current of blood in the large vessels might give rise to a feeble diastolic murmur in a fusiform aneurism. In many cases it is altogether absent; this especially happens in sacculated aneurisms with small mouths, and in those that are much distended with coagula. The absence of sound in a tumour, therefore, must not be taken

as a proof that it is not an aneurism. The sound is usually best heard in aneurisms that are not too fully distended with blood ; indeed, it is usually most distinct when the sac is partially emptied. Thus, for instance, it not unfrequently happens that, in an aneurism of the ham or thigh, no bruit, or but a very faint one, is audible so long as the patient is standing ; but if he lie down, and elevate the limb so as partly to empty the sac, then it may be heard distinctly.

Many of the symptoms that have just been described are peculiar to, and their combination is characteristic of, aneurism, being dependent on the communication that exists between the artery and the sac. Those that result from the pressure of the sac upon neighbouring parts are common to aneurism and to any other kind of tumour ; but, though not of so special a character as those that have just been described, they are of considerable importance in determining the nature of the disease when taken in conjunction with the other symptoms.

**Symptoms of Diffused Aneurism.**—When a sacculated circumscribed aneurism becomes diffused, the sac having given way, but the blood being still bounded by the tissues of the limb, the patient experiences a sudden intense throbbing pain in the part, and usually becomes pale, cold, and faint. On examination, it will be found that the tumour has suddenly and greatly increased in size, at the same time that it has lost its circumscribed outline. The pulsation and bruit become materially diminished in force and in distinctness, and may disappear altogether. The limb may also become œdematous, or may suffer in other ways from the diffused effects of the pressure of the aneurismal swelling upon the neighbouring veins and tissues. At the same time, the circulation in it being greatly obstructed, the limb may become cold and livid, and a sensation of weight and general inutility will be experienced in it. In these circumstances the aneurismal swelling usually becomes harder, in consequence of the coagulation of the blood in the areolar tissue around the sac ; by which indeed the further extension of the disease is arrested, and a fresh boundary is often formed, so as to limit the extravasated blood. If it be left to itself, the tumour will now usually increase rapidly in size, sometimes without, sometimes with much pulsation, so that at last it may so obstruct the circulation through the limb as to occasion gangrene. The tension caused by the rapid increase of the tumour excites more or less acute inflammation in the surrounding structures. As it advances towards the surface, the skin covering it becomes thinned and reddened, the tumour becomes soft and semi-fluctuating, owing to the coagulum breaking down, and eventually external rupture will ensue.

In some cases it happens that, when rupture of the sac takes place, the effused blood, instead of being limited by the surrounding areolar tissue, becomes suddenly and widely extravasated into the substance of the limb. When this untoward accident happens, the shock and local disturbance are very great, and the patient is suddenly seized with very severe lancinating and numbing pain in the part. The pain is most severe in those cases in which the rupture takes place under the deep fasciæ, by which the effused blood is tightly bound down ; and it may be so intense as to occasion syncope. In other instances, faintness occurs from the sudden escape of blood from the current of the circulation into the substance of the part, being most marked in those cases in which the blood is suddenly and largely effused into the areolar tissue. If the

extravasation happen in a limb, this will become greatly swollen, hard, brawny, and cold. The superficial veins are congested, and the circulation in the distal parts of the limb is soon completely arrested by the pressure of the extravasated blood upon its vessels, more particularly the large venous trunks. In consequence of this, moist gangrene usually makes its appearance, and speedily destroys the patient's life.

**Diagnosis.**—The diagnosis of aneurism may in many cases be made with the greatest possible ease by a student in surgery; in other instances it requires a vast amount of care, and the most experienced judgment. The diagnosis is easy when the aneurism is superficial, recent, and circumscribed, the blood in it being fluid, and all the signs well marked. It is often extremely difficult when the aneurism is deeply seated, or, if external, when it is old and filled with coagula; also, if acute inflammation or suppuration have taken place about it, or if it have become diffused.

In making the diagnosis of aneurism we have, in the first place, to ascertain the existence or absence of a tumour; and, after this, to decide whether it be aneurismal or of some other character. Both points, the latter especially, are difficult to determine in internal aneurisms; in the external the doubt is not as to the presence of a tumour, but as to its nature. The *tumours* with which aneurisms may be confounded may conveniently be divided into two classes—those that do, and those that do not, pulsate.

**Every pulsating tumour is not an aneurism.**—Thus there may be pulsation in various kinds of *soft sarcoma*, or in *growths composed of nœvoid tissue*. In such cases as these, many of the signs of aneurism are present: thus the size of the tumour may be diminished by compression, and the distinct influx of blood into it may be felt on the removal of the pressure, the tumour returning to its original size with a soft swelling pulsation; there may also be a bruit, often of a loud and distinct character. But these tumours may generally be distinguished by their not being quite so distinctly circumscribed, and by their being soft, spongy, and elastic, without the sensation of fluid that is met with in some forms of aneurism, or of solid coagula that occurs in others. Again, the bruit is either soft, blowing, and more prolonged, or else sharp and superficial; the pulsation, also, is not so distinct, and is more of the nature of a general swelling and heaving of the tumour than of a distinct thump. Much light is occasionally thrown upon these affections by their being met with in situations where aneurism cannot occur owing to the absence of any arteries of sufficient size to give rise to it, as, for instance, on the head of the tibia or the side of the pelvis; but if a tumour of this kind be situated upon or under a large artery in the usual site of aneurism, then the diagnosis is certainly surrounded with difficulty, and indeed in many cases cannot be made. Several instances have occurred, in which Surgeons of the greatest skill and experience (as Guthrie and Stanley) have ligatured arteries in cases of pulsating sarcoma on the supposition that they had to do with aneurism.

Pulsation may be communicated to a *tumour of a fluid character* seated upon an artery; here the diagnosis, though often difficult, is more readily made than in the last case. Attention to the history of the case, to the impossibility of diminishing the tumour by pressure either directly upon it or on the artery leading to it, its fluctuation, and want of circumscription, will usually indicate its nature. Especial attention should likewise be paid to the facts that the pulsation is a distinct heaving up and down of the tumour, and neither

eccentric nor distensile, and that the swelling may often be wholly or partly separated, by raising it up, from the artery lying beneath it. By attention to these points, abscesses in the axilla, under the pectorals, at the root of the neck, and in other situations where pulsation may readily be communicated to the fluid mass, can be distinguished from aneurisms; yet errors in diagnosis have happened, and will continue to do so, from the intrinsic difficulty of these cases, and from no want of skill or care on the part of the Surgeon: and those will be most charitable in their criticisms of the mistakes of others, who have had most experience of these difficulties in their own practice.

**Tumours that do not pulsate**, either by their own vessels or by those that lie beneath them, are not so readily confounded with aneurism as the class of affections that has just been described.

Yet it must be borne in mind that in some instances even aneurisms do not pulsate, or do so but very indistinctly, having become filled with a dense and firm coagulum. The non-pulsating tumours that chiefly require attention are *glandular swellings*, seated over the carotid artery at the root of the neck, or in the popliteal space. In the neck some thyroid tumours may also closely resemble aneurisms. If these be of a fluid character, their fluctuation, unvarying size, and want of pulsation, sufficiently indicate that they are not connected with the artery, from which they may also frequently be separated, and upon which they may be distinctly moved. If solid, they are usually irregular and nodulated on the surface, and can frequently be detached by the fingers being passed underneath them and raising them from the subjacent vessel. There is great

danger of mistaking an aneurism which is undergoing or has undergone spontaneous cure, and in which consequently there is no pulsation, for a solid tumour of some kind. I have known one instance in which the thigh was amputated for a very painful solid tumour of the popliteal space, which proved to be a consolidated aneurism pressing upon the posterior tibial nerve (Fig. 450).

Aneurisms, more particularly those that are diffused, have not unfrequently been mistaken for *abscesses*; and it is no very uncommon thing for a Surgeon to be called to an aneurism which, under this supposition, has been diligently poulticed, or painted with iodine. I have twice ligatured the external iliac for aneurisms of the groin that had been mistaken for abscesses. Occasionally, the more fatal error has been committed of puncturing the tumour with the view of letting out pus, when none appeared, and, either immediately or after the lapse of a few hours, profuse arterial hæmorrhage ensued. That this accident may arise from the intrinsic difficulties of the diagnosis, is evident from the

Fig. 450.—Section of Aneurism of Calf, undergoing spontaneous cure, mistaken for Tumour. Limb amputated. (a) Black recent Coagulum lying in centre of Laminated Fibrin. (b) Posterior Tibial Nerve stretched.

fact that it has happened to such Surgeons as Desault, Pelletan, Dupuytren, Pirogoff, and many others. I have once seen this accident occur to a Surgeon of considerable experience, who, mistaking a diffused popliteal aneurism for an abscess, opened it with a bistoury, but finding no pus, applied a poultice: alarming hæmorrhage ensued in about forty hours, and I amputated the thigh on the second day after this untoward occurrence.

This difficulty in diagnosis is especially apt to occur in aneurisms which, having become diffused, have ceased to pulsate, have no bruit, are elastic, softened, and diffuent to the feel, and in which the skin has become reddened and inflamed by pressure from within. It is only by careful attention to the history of the case, and by skilful manipulation, that the true nature of the tumour can be made out. But an aneurism may actually become associated with an abscess in one of two ways. Thus it may suppurate, the inflammation taking place in the areolar tissue around it, with swelling, redness, œdema, and heat of the integumental structures, increase of size in the tumour, and probably solidification of it. If this abscess be opened or allowed to burst, dark grumous pus will escape, followed by coagula and masses of decolorized fibrin, and sometimes accompanied, but more usually followed after a lapse of some hours, by a free and perhaps fatal arterial hæmorrhage.

Another form of combination between abscess and aneurism consists in the opening of an artery by ulceration into the cavity of an abscess, so that the blood is projected directly into this from the opened vessel. In cases of this kind—of which the instance that occurred to Liston is a good example—we have the ordinary signs of abscess, usually of a chronic character, to which those of an aneurism are generally superadded suddenly, with great increase in the bulk of the tumour. This accident has been observed chiefly in abscess of the neck, opening up a communication with the carotid artery.

With **rheumatism** and **neuralgia** it would at first sight appear to be difficult to confound an aneurism, but in practice it is not so. I have known several cases in which the lancinating pains of aneurism, more especially when the tumour was internal, have been mistaken for rheumatic or neuralgic affections; and I have even known the pain occasioned by the presence of a large aneurism of the thigh treated for several weeks as rheumatism. In a large proportion of popliteal aneurisms the patient first presents himself for rheumatic pains in the knee; in fact so frequently is this the case that it is a good rule whenever a patient complains of obscure pain in that joint, to examine the ham for an aneurism as the first step towards making a diagnosis. In such cases as these, it is of course obvious that a little care and proper examination will usually enable the Surgeon to avoid an error. The aneurismal may be distinguished from the rheumatic pain by its having a twofold character—being both lancinating and paroxysmal, as well as continuous, aching, and burning. When this kind of pain is persistent, especially about the back, the side of the head and neck, or the arm, it ought always to call the Surgeon's attention to the condition of the neighbouring large vessels.

**TERMINATIONS.**—**Spontaneous Cure** of an aneurism is very rare, but the pathology of this process is of considerable interest, from its bearing upon the cure of the disease by operation. The spontaneous cure may accidentally, though very rarely, occur by inflammation of the aneurism and consequent obliteration of the artery (see Suppuration of Sac). Broca believed that it might occur as the result of inflammation around the sac without suppuration,

and Howard Marsh has recently brought forward a case in which spontaneous cure of a femoral aneurism appears to have resulted from this cause. Most frequently it is by the gradual deposit of laminated fibrin, completely filling up the interior of the sac. This process usually takes place in aneurisms affecting arteries of the second or third magnitude, rarely in those of the aorta (Fig. 451); and it can happen only in sacculated aneurisms, the fusiform not admitting of it, it being necessary that the blood flowing through the sac be somewhat retarded in its passage, so as to favour the adhesion of the colourless corpuscles which is the first step in deposit of fibrin upon the interior of the tumour. This process, which is the same as in the formation of a white thrombus in a vein (see p. 54), is the increase of a natural condition always going on in the sac. In fact in all cases of sacculated aneurism, there is a tendency to spontaneous cure, as shown by a contraction and partial occlusion of the artery *below* the sac, and the consequently diminished circulation through it, by which the deposit of fibrin is increased. At the same time the collateral vessels given off *above* the sac often enlarge to a considerable extent, and thus divert from it blood which would otherwise have passed through it. This condition of the vessel below the sac may be looked upon as the first and most important step towards the consolidation of the tumour. The process is also materially assisted by the mouth of the sac being small. It is probable that in some instances spontaneous cure is determined by a clot detached from the interior of the aneurism becoming arrested in the vessel beyond the sac.

For spontaneous cure to take place, it is by no means necessary that the whole current of blood should be suddenly arrested. If such an accident occur, the aneurismal sac becomes filled with a large dark soft clot, which may yield, if from any cause a pulsating stream of blood be again admitted, but which under favourable circumstances may lead to a complete cure.

If blood continue to circulate through the sac, deposit of laminated fibrin will take place if the impetus with which this fluid is sent into the tumour be considerably diminished. This may happen from the occurrence, in the distal portion of the artery or the mouth of the sac, of some one or other of those conditions that have already been described. So, also, it has been found that in those cases in which two aneurisms are situated upon one artery, the distal one is very apt to undergo partial or even complete consolidation, the blood losing its impetus in its passage through the first sac. Any constitutional case or condition also, by which the impulse of the heart is lessened and the force of the flow of blood through the sac diminished (as the occurrence of

Fig. 451.—Spontaneous cure of Aortic Aneurism. The sac is mostly filled with laminated clot, which is easily distinguished from the soft clot which occupies the mouth of the sac.

phthisis), will greatly favour the deposit of laminated fibrin and the consolidation of the tumour.

As the aneurism undergoes spontaneous cure, the pulsation in it gradually becomes more and more feeble, until it ceases entirely; the bruit proportionately lessens, the tumour becomes harder and smaller, and at last completely consolidated; at the same time, the anastomosing circulation is established in some of the collateral vessels of the limb. Eventually, the solidified tumour shrinks in size, undergoing gradual absorption, with ultimate conversion into a small mass of fibroid tissue.

**Suppuration with sloughing** of an aneurismal sac is not common, but is especially apt to happen in places where the areolar tissue is abundant and lax, as in the axilla, and when the tumour has increased rapidly or become diffused, and thus is causing severe tension of the surrounding parts. The accident is not uncommon also after operations for the cure of aneurism in which the wound is close to or exposes the sac. The inflammation is then merely an extension from that in the wound, and is usually dependent upon septic contamination. Though the process is spoken of as suppuration of the sac, the inflammation commences in the tissues surrounding the aneurism, the sloughing of the sac itself being a secondary process dependent upon its nutrition being cut off by the pus that forms around it. The symptoms of this condition are swelling, tension with heat, throbbing, and redness of the parts around the tumour: the integuments covering it pit on pressure, and are evidently deeply inflamed, at the same time that there is a good deal of fever and general constitutional disturbance. As the suppuration advances, the ordinary signs of acute abscess occur: the skin becomes red and livid at one part, where pointing takes place; and if the Surgeon make an incision into it, or if the tumour burst (as assuredly it will if left to itself), a quantity of pus mixed with large masses of broken-down coagula will be let out. The discharge of the contents of the sac may be followed by a fatal gush of blood. Occasionally, however, as a consequence of the inflammation the artery becomes firmly plugged by a thrombus above and below the opening into the aneurism before the sac gives way, and thus hæmorrhage may be prevented and a spontaneous cure result, the cavity closing like an ordinary abscess after the sloughs and the broken-down clots have been discharged.

**Causes of Death from Aneurism.**—An aneurism may prove fatal in various ways. It does so when internal, most frequently by *pressure* on parts of importance in its vicinity, the patient being destroyed by the exhaustion induced by interference with their functions; this is usually the way in which aneurisms of the aorta occasion death. In other cases the sac bursts into the pericardium, pleura, or peritoneum, and sudden death may occur from loss of blood; or asphyxia may result from its giving way into the trachea. Then, again, death may result by the occurrence of *syncope*, more especially if the aneurism be of large size, and situated near the root of the aorta. *Embolism* of the cerebral arteries may occur in consequence of the detachment of a clot. External aneurism most commonly proves fatal by *rupture of the sac*: this may either take place into the interior of a limb, giving rise to one or other of the diffused forms of aneurism, and terminate fatally by the induction of syncope or gangrene; or an aneurism may kill by rupture occurring externally, on one of the surfaces of the body.

The rupture of an aneurism is not always immediately fatal, the aperture in

the sac being plugged up by a mass of coagulum, as happened in the case represented in Fig. 452; on the gradual detachment of the deeper portions of this coagulum the bleeding may recur in small quantities at intervals, and more or less speedily carry off the patient. On the mucous surfaces, as of the oesophagus or trachea, rupture occurs in a similar manner (Fig. 452). On the serous surfaces, as into the pleura or pericardium, the aneurism may burst by a fissure or by a stellate opening (Fig. 453) forming in the membrane. An aneurism has been known to give way and discharge blood for some weeks before it proved fatal; and it may even happen that, after the rupture has occurred, no hæmorrhage may take place, but death may result from the pressure of the tumour. Thus, in the case of Liston, the sac of the aneurism which caused the death of that great Surgeon had actually given way, a mass of coagulum projecting from it into the trachea; yet death resulted from pressure upon the inferior laryngeal nerve, and not from hæmorrhage.

The **Treatment** of aneurism is constitutional and local. In many cases, as in the various forms of internal aneurism constitutional treatment can alone be

Fig. 452.—Aperture in Oesophagus produced by Pressure of an Aortic Aneurism.

Fig. 453.—Stellate Rupture of an Aortic Aneurism into Pericardium.

employed; and in all cases of external aneurism it should be had recourse to as an adjunct to any local measures that are adopted.

In the **Constitutional or Medical Treatment** of aneurism, the object is to bring about a condition similar to that in which spontaneous cure of the disease takes place, and, indeed, to put the patient and the part in the most favourable state for nature to consolidate the tumour; and, though it may not be possible in most cases to effect a cure in this way, the disease may in all events be palliated, and its progress retarded. The sacculated is the only form of aneurism that can ever be cured by constitutional means; in the fusiform variety, all that can be done is to retard the progress of the disease.

The principal objects to be kept in view are, first to lessen the force of the heart, so as to diminish the pressure upon the arterial coats; and, secondly, so to modify the condition of the blood as to dispose it to the deposit of its fibrin. In carrying out these indications, it should be borne in mind that there are two opposite conditions of the system in which aneurism occurs: in one there is a plethoric, and in the other an anæmic tendency. The plethoric and irritable state of system occurs chiefly in young subjects, in whom the progress

of the disease is acute and rapid, attended with much impulse and excitability of the heart, and throbbing of the arteries generally. The other condition of the system is found usually in elderly people, with a feeble pulse, a quiet heart, and a tendency to anæmia; in such a habit of body the disease makes slow progress. In these opposite conditions it is perfectly clear that the same plan of treatment cannot succeed; and that the constitutional means must be modified according to the state of the patient.

In the *acute* or *hyperæmic state*, the plan of treatment originally introduced by Valsalva, and hence called by his name, may advantageously be employed, in the modified manner that has been recommended and adopted by some modern Surgeons. Pelletan, Hodgson, and Tufnell have reported very favourably of this treatment, and I have seen several instances in which it has proved decidedly beneficial. As recommended by Valsalva, this method of treatment was intended to carry out two important points: 1, by a process of gradual starvation and depletion to reduce the quantity of blood in the system, the force of the heart, and consequently the pressure exercised upon the walls of the aneurism; and, 2, after the patient had in this way been reduced, the plasticity of the blood was to be improved by feeding him up in a gradual and careful manner, so that the tendency to the deposit of laminated fibrin might be increased. Valsalva endeavoured to carry out the first of these objects by subjecting the patient to small and repeated bleedings, and by gradually reducing the quantity of food that was daily taken, until it was lowered to half a pound of pudding in the morning, and a quarter of a pound in the evening. In this way the patient's strength was reduced until he could scarcely be raised up in bed without fainting; the quantity of food was then gradually augmented, so that the plasticity of the blood might be restored. It is seldom that Surgeons carry out Valsalva's plan of treatment in the precise manner indicated by him; it is generally found to be more convenient to modify it somewhat according to the circumstances of the case, though the principles on which it is conducted are essentially the same.

In adopting any constitutional treatment in cases of aneurism, the first and most essential to be attended to is to keep the patient perfectly quiet in bed and free from all excitement. The diet should be very carefully regulated, being gradually reduced in quantity, and consisting principally of farinaceous food, with a very small quantity of meat, little liquid, and a total absence of stimulants. Perhaps the best regimen is that recommended by Bellingham, consisting of two ounces of bread and butter for breakfast, two ounces of bread and the same quantity of meat for dinner, and two ounces of bread for supper, with about two ounces of milk or water with each meal, or occasionally sipped in small quantities. At the same time purgatives should be administered, especially such as give rise to watery stools, and remove obstructions of the portal system; with this view a scruple of the compound jalap powder may be given twice a week. In some cases, if the heart's action be particularly strong, recourse may advantageously be had to small bleedings from time to time.

Iodide of potassium, in doses varying from five to thirty grains three times a day, has been largely used in cases of intrathoracic and abdominal aneurism, and its good effects lend some weight to the supposed syphilitic origin of many aneurisms. In a large proportion of the cases thus treated, the sufferings of the patients have been relieved; there has been diminution of the size of the sac, and in several instances the cure has apparently been perfect. The

enforcement of the recumbent posture is of great importance in this treatment. There certainly appears to be sufficient evidence to warrant a trial of the iodide in the constitutional treatment of aneurism.

By judiciously carrying out these plans of treatment and modifying them according to the circumstances of the case, consolidation of the aneurismal tumour may occasionally be produced ; or, if this be not obtained, the progress of the disease will be very materially retarded.

When aneurism occurs in *old, feeble, or anæmic persons*, a lowering plan of treatment is altogether inadmissible : here, such a course must be adopted, as will improve the plasticity of the blood, and regulate the action of the heart. With this view, complete rest, the administration of the preparations of iron, a dry but nourishing meat diet, and the occasional employment of opiates to relieve pain and to quiet the system, will be attended with the best results. In aneurism occurring in elderly people and amongst the poorer classes, this plan is perhaps more successful than any other.

In the **Local Treatment** of aneurism but little can be done with the view of checking its progress, except by the employment of direct surgical means. The application of ice to the surface of the tumour is said to have acted beneficially in some cases ; but it is a painful remedy, and may occasionally be attended with sloughing of the skin to which it is applied. When the pain attending the increase of the tumour is considerable, much relief may be obtained from the hypodermic injection of morphia, the application of belladonna plasters, or the use of an embrocation composed of equal parts of oil and of the strong tincture of aconite. These means comprise the only local measures that can be adopted in those cases of internal aneurism which are beyond the reach of surgical interference.

#### SURGICAL TREATMENT OF ANEURISM.

In all those cases in which it is possible to delay with safety, no surgical proceeding should be undertaken for the cure of aneurism until the patient has been subjected to proper constitutional treatment for some time ; for, as the occlusion and consolidation of the sac, after surgical procedure, depend on the same conditions being induced that are successful after medical treatment, the same constitutional means should be adopted in the one case as in the other. Before proceeding to the employment of any direct surgical means for the cure of an external aneurism, it is necessary to ascertain that there is no internal aneurism present, and that the heart is free from disease. From want of this precaution, it has happened that patients have died on the operating table at the moment when the artery was being ligatured, or shortly afterwards.

There is not a more interesting chapter in the history of Operative Surgery than that which records the changes that have taken place and the progress that has been made in the treatment of aneurism.

The older Surgeons were either afraid to meddle at all with aneurism, and amputated the limb affected by it, or tried to restrain the progress of the disease by tight bandaging and direct pressure upon the tumour, or had recourse to the difficult and dangerous operation of laying open the sac and ligaturing or applying the actual cautery or styptics to the diseased artery on each side of the opening in it. In 1785, John Hunter substituted for these dangerous methods of treatment, the simpler and more scientific procedure of ligaturing the artery in a distant part of its course,

above the sac, and thus directly cutting off the influx of blood into the tumour. \*This undoubtedly constituted one of the greatest and most direct advances in Surgery that has ever been made by the single act of one man, and for more than half a century the "Hunterian Operation" continued to be almost the sole method of treating this formidable disease. It was not until 1841—42 that the Dublin Surgeons showed by practice and experiment that an aneurism could be cured by simply occluding for a time the artery leading to it by the pressure of an instrument applied on the proximal side of the sac. Soon after Vanzetti still further simplified the treatment by substituting the pressure of the finger for that of an instrument. In addition to this, the fact was established, that in some cases adequate compression of the vessel and sac might be effected by simple flexion of the limbs. Thus, then, a progressive simplification has taken place in the treatment of aneurism, and, still more recently, the sphere of the applicability of compression has been greatly extended by conducting it during prolonged anæsthesia.

We will now proceed to consider in detail the various methods of treatment. They are as follows: 1. Ligature above and below the aneurism after laying open or excising the sac; 2. Ligature of the artery on the cardiac side; 3. Ligature of the artery on the distal side; 4. Compression by instruments; 5. Digital compression; 6. Compression by the elastic tourniquet; 7. Flexion of the limb; 8. Acupressure; 9. Manipulation; 10. Galvano-puncture; 11. Injection of the sac with coagulating fluids.

All these various methods of treatment, however they may differ in their details, have, with the exception of the first, the same great principle in view, viz. the consolidation of the aneurismal tumour by the deposit of coagulum within it. When the process adopted is of such a nature as to lead to the slow deposit of coagulum, this will be found to be pale, firm and laminated—the *active* clot of Broca. When the deposit is rapid, it will be dark, soft and homogeneous—the *passive* clot.

**Ligature.**—The manner in which the ligature should be applied, and the various cautions respecting its use, have been sufficiently discussed (Vol. I., p. 427 *et seq.*). The question as to the part of the vessel to which it should be applied in aneurism, remains for consideration; and this involves some important points.

**Situation.**—There are three situations in which the ligature may be applied: 1, *above and below the sac*, by the old operation; 2, *on the cardiac side* of the sac, by Anel's (Fig. 454) or Hunter's (Fig. 455) operation; 3, *on the distal side* of the sac, by Brasdor's operation (Fig. 456).

1. **The Application of the Ligature on both sides of the Aneurismal Sac** is seldom practised at the present day, except in traumatic aneurisms, in which it is frequently the best means of treatment, as has been mentioned in Chap. XV. Vol. I. The older Surgeons, however, were acquainted with this mode only of treating aneurisms, which was practised by Antyllus in the third or fourth century, and is often called by his name. The mode of applying the ligature to both sides of the sac is as follows. After having arrested the circulation through the aneurism, by compressing the artery leading to it, either by means of a tourniquet, or, where that is not applicable, by the pressure of an assistant's fingers, the Surgeon slits up the sac, and turns out the coagula and masses of laminated fibrin. Then, passing a probe, or a steel bougie if the vessel be large, upwards and downwards into the artery, through the mouth

of the sac, he cleans the vessel by dissecting away the part of the sac which overlaps it, and ties it on each side, immediately above and below the aperture. This operation, as performed by the older Surgeons on any of the larger arteries, as the popliteal, was not only so difficult in itself that they were seldom willing to undertake it, but was so fatal in its results, being commonly followed by secondary hæmorrhage, or by diffuse inflammation, suppuration, and gangrene that recovery after its performance was considered a marvel, and amputation was generally preferred. At the present time, however, the difficulties are much diminished by the bloodless method of operating, and the subsequent dangers by the improved methods of treating wounds. The operation may, therefore, be undertaken with less hesitation as a last chance of saving a limb in which an aneurism has become diffused. Its applicability will be further discussed with the special aneurisms in the treatment of which it has been employed.

Recently the old operation has been modified by completely excising the sac and ligaturing the artery above and below it. Kuebler has collected 40 cases in which complete extirpation was practised. This list, however, includes 29 traumatic aneurisms. Only one case ended fatally; gangrene of the foot occurred in a case of femoral aneurism, but secondary hæmorrhage was not recorded in any instance. The treatment is obviously impracticable in many situations, and although it has been successfully adopted in cases of femoral, popliteal, axillary and brachial aneurism, it is hardly likely, on account of the difficulty of the operation, to be extensively practised. In certain cases it is an available method of treatment after others have failed; of Kuebler's cases 11 had been unsuccessfully treated by compression, and five by proximal ligature. In those rare instances in which aneurisms are met with on the smaller arteries, such as those of the forearm, complete excision would probably prove the most efficient treatment.

Fig. 454.—Anel's Operation. Fig. 455.—Hunter's Operation. Fig. 456.—Distal Operation.

2. **The Ligature of the Artery on the Cardiac Side of the Aneurism,** without opening the sac, was first done by Anel, in the year 1710, in a case of brachial aneurism. This operation, though attended with the risk of wound or inflammation of the sac, which was in close proximity to the seat of ligature, constituted a considerable advance in the treatment of the disease, inasmuch as it did not necessarily lead to the opening up of the aneurismal tumour, and to the dangers inseparable from that mode of procedure. As Anel, however, performed his operation as a mere matter of convenience in a particular case, and without the recognition of any new principle of treatment being involved in it, it attracted but little attention at the time, and does not appear to have been repeated by any of the Surgeons of his day.

It was reserved for John Hunter to make the great improvement of *ligaturing the artery at a distance from the sac*. In this way the objections to Anel's operation were avoided: for though, like Anel, Hunter tied the artery on the

cardiac side only of the sac, yet he differed from him in doing so at a considerable distance above the tumour, where the application of the ligature would be attended with less risk of hæmorrhage, and without the danger of opening or exciting inflammation in the sac, which is inseparable from Anel's operation.

The following are the reasons, given in Everard Home's own words, that induced John Hunter to adopt the operation which is now generally known in surgery as the *Hunterian*. "Mr. Hunter proposed, in performing this operation, that the artery should be taken up at some distance from the diseased part, so as to diminish the risk of hæmorrhage, and admit of the artery being more readily secured should any such accident happen. The force of the circulation being thus taken off from the aneurismal sac, the cause of the disease would, in Mr. Hunter's opinion, be removed; and he thought it highly probable that, if the parts were left to themselves, the sac, with the coagulated blood contained in it, might be absorbed, and the whole of the tumour removed by the action of the animal economy, which would consequently render any opening into the sac unnecessary." Hunter's first operation was performed in December, 1785, in a case of popliteal aneurism. The femoral artery was ligatured rather below the middle of the thigh, underneath the sartorius muscle.

The **Effects produced upon an aneurism** by the ligature of the artery according to the Hunterian method, deserve careful attention. The immediate effect, on drawing the ligature tight, consists in a cessation of pulsation and bruit in the tumour, which at the same time diminishes in size, becoming partly emptied of its blood. The supply of blood to the limb being in a great measure cut off, it becomes numb and cold, with a diminution of muscular power. The more remote effects consist in an increase of the activity of the collateral circulation, by which the vitality of the limb is maintained. At the same time, and, indeed, in consequence of this, the temperature of the limb often rises, until it becomes higher than that of its fellow.

The consolidation of the aneurism begins as soon as the ligature is applied, and is usually completed in a few days, by changes taking place within it similar to those that occur in the spontaneous cure of the disease. This important change is effected by the gradual deposit of stratified fibrin in concentric layers within the sac, and occasionally by the sudden coagulation of its contents. For the cure to be accomplished by the deposit of laminated

Fig. 437.—Femoral Artery ligatured for Popliteal Aneurism, obliterated at *a*, the site of the Ligature, and at *b*, where the Tumour has become consolidated and absorbed: between these points the Artery is open, and collateral branches enlarged.

fibrin, it is necessary that, though the direct flow of blood through the tumour be arrested by the ligature of the main trunk, some should yet be carried into it by collateral channels. This is a condition very favourable to the success of the ligature: for, if it happen that all the flow of blood through the tumour is arrested, coagulation of that which happens to be contained in it will ensue, and a soft yielding clot be formed, which is more likely to lead to unfavourable results than the firm products of slow coagulation. It is of importance to

observe that the proper consolidation of the aneurismal tumour, by the deposit of laminated fibrin, will occur even though a very considerable quantity of blood continue to flow through it. In the Museum of University College there is an exceedingly interesting preparation that is frequently referred to in connexion with this point. It is one in which Charles Bell ligatured the femoral artery for popliteal aneurism. The patient died a week after the operation, of erysipelas; on examination, it was found, that the femoral artery was double, and that, though only one portion of the vessel had been ligatured, the tumour, which continued to be supplied by the other branch, was completely consolidated. It is doubtful, however, in this case whether the consolidation was due so much to the diminished influx of blood to the tumour consequent upon ligature of artery as to the feebleness of the heart's action before death and possibly to some blood-change induced by the septic disease of which the patient died. After the aneurismal sac has been thus occluded, it progressively diminishes in size, and is at last converted into a small mass of fibroid tissue. The artery that has been ligatured becomes closed at two points—at the part deligated (Fig. 457, *a*), and where it communicates with the sac (Fig. 457, *b*). In both these situations, it will be found to be converted into fibroid tissue; whilst between them there is an open space, through the medium of which the collateral circulation is freely carried on. Savory has collected 17 complete specimens from the London Museums illustrating the ligature of the femoral artery in Scarpa's triangle for popliteal aneurism. In 13 specimens the artery below the point ligatured is pervious throughout, and in 11 of these the aneurism was cured; in 4 specimens the vessel was to a greater or less extent pervious, the aneurism in all being consolidated.

**3. Distal Ligature.**—In some cases in which the ligature cannot, for anatomical reasons, be applied on the proximal side of the aneurism, as in the arteries about the root of the neck, it was recommended by Brasdor, a French surgeon about the middle of the last century, that the vessel should be tied on its *distal* side. This operation, originally proposed by Brasdor, was first performed by Deschamps in 1799 at La Charité in Paris in a case of femoral aneurism. In principle, it resembles the Hunterian operation, the object being to arrest so much of the flow of blood through the sac that the consolidation of this may take place in the usual way, by the deposit of laminated fibrin. In the Hunterian operation, this is effected by deposit from the lessened quantity of blood that flows through the sac; in the distal operation, it is sought to be accomplished in the same way, and the success of the operation must necessarily depend, in a great measure, upon the extent to which the flow of blood through the sac is interfered with. This operation, however, is rarely successful; for, independently of the ordinary dangers resulting from the application of the ligature to a large vessel, the sac will continue to receive the direct impulse of, the blood that is driven into it. The natural result of the ligature would be to increase the general arterial tension and with it that of the sac; but, as Holmes points out, the enlargement of the collateral circulation opens, as it were, "side-sluiques" to relieve this pressure, and consequently after a few hours or days the sac is usually found to be less tense than before the operation. Hence the progress of the aneurism may be arrested for a time, but it will often speedily increase again, and may perhaps eventually destroy the patient by suppuration and sloughing. Of 38 cases in which this operation was practised on the carotid artery, in 25 a fatal result

more or less speedily followed the operation: in the remaining 13 cases the patients survived the effect of the ligature of the artery, though in very few, if any, of the cases were they cured of the disease for which the operation was performed. This operation will be considered more in detail in speaking of the particular cases in which it has been practised (see Chap. XLIV.).

**Indications and Contra-indications of Ligature.**—Ligature of an artery for aneurism, by the Hunterian method, succeeds best in those cases in which the tumour is circumscribed, of moderate size, slow in its growth, having a tendency to consolidation, and unaccompanied by much oedema of the limb. When the aneurism is undergoing spontaneous cure, no surgical interference should be employed, but the case should be left to nature. In this way it occasionally happens, during the preparatory treatment of the disease, that the aneurism becomes consolidated.

Before the Surgeon proceeds to cut down upon an artery with the view of tying it, he should, as far as practicable, ascertain by a careful examination of it, whether it appears to be in a healthy state at the point at which he is about to tie it. He should feel along its course to ascertain if it be smooth, easily compressible, and natural to the feel; if it be hard, incompressible, indicative of calcification; if it feel broader than natural; if a bruit be heard in it on applying the stethoscope. If there be evidence of degeneration or dilatation of its coats, great caution should be used in attempting to ligature it. Should the deligation of a diseased artery become unavoidable, the chromic catgut, or the tendon ligature, would probably be the best material for the purpose.

It has occasionally happened to Surgeons that they have cut down upon an artery with the intention of tying it, and found it in so diseased a state that the application of the ligature was impracticable, and that it became necessary to close the wound without completing the operation. Liston and Aston Key have both had the candour to record such cases. In one case that happened to me in which it was thought necessary to tie the superficial femoral for popliteal aneurism, I found, on cutting down on the artery, that there was a small aneurismal dilatation just below the origin of the profunda, and a tubular dilatation of the artery below this, rendering the application of a ligature utterly impracticable. I afterwards tied the external iliac, but unsuccessfully. It must also be remembered that, in such cases as these, the vein is usually adherent, and consequently liable to perforation in passing the aneurism needle between it and the artery. And even could deligation be practised, there would be considerable danger of secondary hæmorrhage at an early period in an artery incapable of obliteration in the normal way.

No operation should be performed when there is any serious disease of the heart, or in cases of multiple aneurism where the second tumour is situated internally; but it has happened that two aneurisms in one limb, as of the popliteal and femoral arteries, have been cured by one ligature applied to the external iliac. Two aneurisms seated in corresponding parts of opposite limbs, affecting, for instance, the two popliteal arteries, may be successfully operated upon. But, if two aneurisms be seated on different parts of the body, as the axilla and groin for instance, at the same time, extensive disease of the arteries is usually indicated, and it certainly would not be expedient to operate.

In certain cases, the Hunterian operation seldom succeeds. This happens in those instances in which it is necessary to apply the ligature very close to the sac, so as indeed rather to perform Anel's operation, as here there is the danger of wounding the sac or of inflammation subsequently occurring around

it, and of interfering with the collateral circulation of the limb. Those cases, also, in which the aneurism is very acute in its progress, increasing rapidly with forcible pulsation, having very fluid contents, and a large mouth to the sac, into which the blood is consequently driven in a full wave at each pulsation of the heart, are rarely favourable for the use of the ligature, inasmuch as deposit of coagulum seldom occurs. When the aneurism is situated in the midst of loose and very yielding tissues, as in the axilla, where it readily expands to a large size, not being bound down by the surrounding parts, suppuration and sloughing of the sac are especially apt to occur after ligature. When it is diffused widely through the limb, with coldness and a tendency to incipient gangrene, the circulation of blood through the part is so much obstructed that deligation of the vessel will in all probability arrest it entirely, and thus produce mortification. When arteries can be felt to be calcified, it is a question whether they can safely be ligatured, as in all probability the changes necessary for their occlusion will not take place. Porter, however, recommended that the ligature should be applied in such cases, though I cannot but doubt the propriety of this advice. When inflammation has been set up in the sac, it is a debatable question whether the ligature should be applied or not. In these cases I agree with Hodgson, that the artery should be tied; for even if the sac eventually suppurate, there will be less risk to the patient if this occur after the application of the ligature, than if it happen while the artery leading into the tumour is pervious. If suppuration have already taken place around the sac, the application of the ligature above the inflamed tumour on the point of bursting would be worse than useless. In such cases, the line of practice must be determined by the seat of the aneurism. If this be in the axilla, groin, or neck, it should be laid freely open, the coagula scooped out, and the artery tied above and below the mouth of the sac—a most formidable and doubtful operation, but the only one that holds out a chance of success. If the aneurism be in the ham or calf, amputation would probably be the best course to pursue.

In some instances, there is no resource left to the Surgeon but to amputate. 1. Amputation must be performed when the aneurism is associated with carious bone or a diseased joint, as when a popliteal aneurism has produced destruction of the knee. 2. If the aneurism have attained so great a size that it has already seriously interfered with the circulation through the limb, as indicated by considerable oedema, lividity, and coldness of the part, with distension of the superficial veins, it is a question whether the application of the ligature may not immediately induce gangrene, and whether the patient would not have the best chance of recovery by submitting to amputation at once; this is more particularly the case when the aneurism, whether previously large or small, has become diffused and gangrene is impending, when removal of the limb must not be delayed. 3. If gangrene have actually supervened and the patient's strength be sufficient to bear the operation, amputation should be done without delay. 4. If a diffused aneurism in the lower extremity, whether suppurating or not, have been opened by mistake for an abscess, an attempt may sometimes be made to save the limb by laying open the sac and ligaturing above and below its mouth, but more often immediate amputation is required.

The mortality after ligature of the larger arteries for aneurism is very considerable. Thus, in 256 cases of ligature of the larger arteries for aneurism, collected and tabulated by Crisp, it would appear that the mortality amounted to about 22 per cent. And Porta finds that, among 600 cases of

ligature of arteries for diseases and injuries of all kinds, the mortality amounted to 27 per cent. It must be borne in mind that these are collections of reported cases, and that, if the unrecorded cases could be got at, the rate of death would, in all probability, be found to be much higher even than that above stated.

**ACCIDENTS AFTER LIGATURE FOR ANEURISM.**—The accidents that may follow the application of the ligature in a case of aneurism, are : 1, Secondary Hæmorrhage from the seat of ligature ; 2, the Continuance or the Return of Pulsation in the Sac ; 3, the occurrence of Suppuration and Sloughing of the Tumour, with or without hæmorrhage from it ; and 4, Gangrene of the Limb.

1. **Secondary Hæmorrhage** from the seat of ligature presents nothing peculiar, and has already been discussed in Vol. I., p. 453.

2. The **Continuance or Return of Pulsation** in an Aneurismal Sac after successful obliteration, by the ligature, of the artery leading to it, is an interesting phenomenon, and one that deserves much attention. When the Hunterian operation is successfully performed, though the pulsation in the sac be entirely arrested, a certain quantity of blood continues to be conveyed into and through it by the anastomosing channels, and it is from this that the laminated fibrin is deposited by which the consolidation of the tumour is ultimately effected. The stream of blood furnished by regurgitation, or by transmission through the smaller collateral channels, is continuous, and not pulsatory ; occasionally, however, it is transmitted in sufficient quantity by some more than usually direct and opening anastomosing branch, and thus gives rise to a continuance or to a return of the pulsation. It is interesting to observe that, in some of the cases in which this has happened, there has been a return of the bruit, but in the majority no sound appears to have been emitted.

The *period* of the return of the pulsation in the sac after the ligature of the artery varies greatly. In the great majority of cases—at least two-thirds of those in which it has happened—a certain degree of thrill or indistinct pulsation has been found in the sac shortly after the application of the ligature ; at all events within the first twenty-four hours. This may be looked upon as being rather a favourable sign than otherwise, as it is indicative of the free state of the collateral circulation, and it generally soon disappears spontaneously, the sac undergoing consolidation. Next in order of frequency are those cases in which the pulsation returns in about a month or six weeks after the ligature of the artery, the collateral circulation having been fully established, and, after continuing for some length of time, gradually ceases. It more rarely happens that the pulsation returns between these two periods ; that is to say, about ten days or a fortnight after the application of the ligature ; though in some instances the slight vibratory thrill, scarcely amounting to a pulsation, which perhaps is perceptible a few hours after an artery has been tied, gradually strengthens at the end of a week or ten days into as distinct and forcible a beat as had been noticed before the operation. In some rare instances the pulsation has re-appeared after the lapse of some months, the aneurismal tumour having in the meanwhile undergone absorption ; then indeed it may with justice be looked upon as constituting a *secondary aneurism*, and as indicating a recurrence of the disease.

The *cause* of the continuance or of the return of the pulsation in an aneurismal sac, must be looked for in too great a freedom of the collateral circulation. Indeed, it is an essential requisite for the manifestation of this phenomenon, that there should be so free and direct a communication between

the artery on the proximal side of the ligature, and that portion of the vessel situated between the ligature and the sac, or the sac itself, as to enable the impulse of the heart to be transmitted in a pulsatory manner into the tumour. No regurgitant blood coming upwards from that portion of the artery which is distal to the sac, however free it may be, can communicate an impulse, as it never flows *per saltum* except in the special case of a continuous circle of large anastomoses, such as are met with between the arteries within the skull, or in the palmar and plantar arches. If any of the direct collateral or feeding vessels happen to be sufficiently large at the time of the operation to transmit the wave of blood, the pulsation in the sac will be continuous, or will return almost immediately after the application of the ligature. If they be at first too small for this, they may become enlarged as part of the anastomosing circulation, and then the pulsation will return as soon as their calibre is sufficient to transmit the heart's impulse. Besides these conditions it is not improbable, as was supposed by Porter, that certain states of the blood may, from causes with which we are unacquainted, render it less liable than usual to coagulate, and thus dispose to a return of the pulsation in the sac, which remains filled with fluid blood.

The phenomenon under consideration has been noticed in all parts of the body after the performance of the Hunterian operation, though it occurs with different degrees of frequency after the ligature of different arteries, and is certainly of more common occurrence after operations for carotid aneurism than for any other form of the disease. Thus, of 31 cases in which the carotid artery was tied for aneurism, I find that pulsation in the tumour continued or returned in 9 instances; whereas of 92 cases of inguinal aneurism, in which the external iliac artery was ligatured, the pulsation recurred in 6 cases only; and in several of these it is interesting to note that there were two aneurismal sacs in the same limb—one in the groin, the other in the ham; and that the pulsation, though permanently arrested in the popliteal, recurred in the inguinal aneurism. In the ham and axilla, pulsation occasionally, though very rarely, recurs. This difference in the frequency of the recurrence of pulsation in different aneurisms is evidently owing to the different degrees of freedom of communication that exist between the sac and the collateral branches in various forms of the disease: thus in a carotid aneurism, the impulse of the heart may at once be brought to bear upon the contents of the sac, through the medium of the circle of Willis. But, in the case of inguinal, femoral, or popliteal aneurism, the anastomoses, consisting rather of the intercommunications of terminal branches than of open communications between large trunks, are less likely to transmit the blood in a pulsatory stream. For the same reason—the great freedom of the communication between the vessels of opposite sides—the pulsation has more frequently been found to continue uninterruptedly and distinctly, though reduced in force, after the ligature of the artery in carotid aneurisms, than in those in any other situation. The cases in which it returns after the cessation of a few hours only are perhaps as frequent in the groin and ham as in the neck. In those instances in which the pulsation returns within the first twenty-four hours after the ligature, it usually ceases again in a few days, though it sometimes continues a week or two. When it recurs at a later period, it is apt to last somewhat longer. Compression antecedent to the ligature may so enlarge the collateral vessels as to favour a continuance or return of pulsation. I have once known the pulsation continue, though very much lessened, in a popliteal aneurism, after

ligature of the superficial femoral, in a case in which compression had been tried unavailingly for nearly three months. In another case, in which I tied the external iliac artery for popliteal aneurism, owing to the superficial femoral being too diseased to admit of a ligature, the pulsation ceased completely for a time as I was tightening the ligature, but then returned, and became very marked in a few hours. In this case compression had been unavailingly employed before the artery was tied.

The *prognosis* of these cases is on the whole favourable, but few of them having eventually proved fatal. Of 26 patients in whom pulsation occurred, I find that three died; and in all of these the fatal result was occasioned by inflammation and sloughing of the sac. In all three instances, the pulsation recurred within the first twenty-four hours. When it returns at a more advanced period, there is little risk to the patient, as it is usually readily amenable to proper treatment.

A **Secondary Aneurism** is of extremely rare occurrence: indeed I believe there are only two unequivocal instances of this affection upon record, both of which took place in the ham; the original tumour having disappeared entirely after operation, the secondary disease made its appearance after a lapse of six months in one case, and in the other after four years. It is of importance to distinguish between a secondary aneurism and secondary or recurrent pulsation in an aneurismal sac. The term "*secondary aneurism*" should be restricted to those cases in which an aneurism appears in the site of a former one, which has undergone consolidation and absorption. The question may be raised, whether aneurisms of the kind are in reality secondary or whether they may not originate in the dilatation of a portion of the artery contiguous to the seat of the former disease. It is certainly not easy to understand how an aneurism that has once undergone consolidation and absorption can again become dilated into a pulsating tumour; and I think it most probable that, although the secondary aneurism may be found in the same region as the primary one, it in reality takes its origin from a slightly higher part of the artery, where the same changes may have been in progress that determined the disease in the first instance. Double aneurism thus arising is, indeed, occasionally met with in the ham as a primary disease. I have seen a popliteal aneurism associated with another at or immediately above the aperture in the adductor magnus: if the artery in such a case as this had been tied before the second tumour had attained any magnitude, we can easily understand how, when this became dilated, it might have been considered to be a new enlargement of the original sac, whereas it was in reality a new aneurism forming in close vicinity to the old one.

**Enlargement of an aneurismal sac without pulsation**, after the ligature of the artery leading to it, is an interesting phenomenon, and one that might cause the true nature of the tumour to be misunderstood, as it closely resembles in its slow and gradual increase the growth of a malignant tumour. It is occasioned by the distension of the sac by regurgitant blood brought into it through the distal end of the vessel, without sufficient force to cause pulsation, though sufficient to occasion a gradual increase in the size of the swelling.

**Treatment of Recurrent Pulsation.**—In the majority of cases secondary pulsation ceases of itself in the course of a few days or weeks from consolidation of the sac, in the same way as after ligature of the artery, by the deposition of laminated fibrin. This tendency to consolidation may be much

assisted by means calculated to lessen the force of the impulse of the blood into the sac, such as compression of the artery above the point ligatured, rest, the elevated position, and the application of cold to the part; cold, however, must be carefully applied, lest, the vitality of the limb being diminished, gangrene be induced. At the same time, direct pressure may be made upon the sac, so as to moderate the flow of blood into it: this has in many cases succeeded in producing consolidation of the tumour, and may most conveniently be applied by means of a compress and narrow roller. This plan is especially adapted to popliteal and inguinal aneurisms, but cannot so well be exercised upon those situated in the neck. Care must be taken that the pressure be not at first too powerful, lest gangrene result; the object is not so much to force out the contents of the tumour, or to efface it, as simply to restrain and moderate somewhat the flow of blood into it. Should the aneurism be so situated that pressure can be exercised upon the artery above the point ligatured, this should be had recourse to either by the finger or by instrument, and will be both safer and more likely to be effectual than direct pressure. I succeeded in this way in curing a very remarkable case of recurrent pulsation in a popliteal aneurism. The patient, a man about thirty-five years of age, was admitted into University College Hospital for an aneurism, about the size of an orange, in the right ham. Treatment by compression was employed, without any effect being produced on the tumour, for three months. During this period compression was employed in all forms—by Carte's instrument, the weight, the finger, and flexion. I then tied the superficial femoral artery in Scarpa's triangle with a hemp ligature. The pulsation was arrested in the tumour when the ligature was tied, but returned in a slight degree in about an hour, and slowly increased, never becoming at all forcible, but being very distinct. The ligature separated on the fourteenth day. The limb was bandaged, and a pad applied over the aneurism without any effect; and the limb was raised, but still the pulsation continued. Carte's compressor was again applied to the common femoral artery, and used for about three hours in an intermittent manner, when the pulsation finally ceased.

In the event of the pulsation not disappearing under the influence of pressure, conjoined with rest, dietetic means, and the local application of cold, the following courses are open to the Surgeon: 1, To ligature the vessel between the situation of the previous operation and the aneurism; 2, To perform the old operation of laying open the sac; 3, To excise the aneurism; and 4, To amputate, if the aneurism be situated in a limb.

The evidence afforded by recorded cases and the consideration of the condition of the vessel after ligature seem to suggest that the most hopeful treatment is to ligature the artery lower down, viz., between the situation of the previous operation and the aneurism. The recurrence of pulsation in most cases probably depends upon the free entry of blood, brought by the collateral circulation, into the still patent vessel above the sac. In a case of recurrent pulsation in a popliteal aneurism after ligature of the femoral artery in Scarpa's triangle Savory successfully ligatured the popliteal artery about two inches above the sac; two catgut ligatures were applied and the vessel divided between them. In a similar case under the care of T. Smith ligature of the superficial femoral in Hunter's canal failed to arrest the recurrent pulsation. Subsequently, the popliteal artery was ligatured and

divided an inch above the aneurism, when the pulsation ceased and the sac rapidly diminished.

In the event of religature proving unsuccessful the Surgeon must choose between laying open or completely excising the aneurism, and amputation. The operation of opening the sac, turning out its contents, and ligaturing the vessel supplying it, is in any circumstances a procedure fraught with danger to the patient, and full of difficulty to the Surgeon, even when he knows in what situation to seek the feeding vessel. How much greater then must the difficulty be, when he is in uncertainty as to the point at which the artery enters the sac, and cannot know whether there be more than one arterial branch leading into it. Still, if the limb be made bloodless by Esmarch's method, these difficulties may be overcome, and it is well, therefore, to attempt the operation whenever possible, falling back at once on amputation if it cannot be brought to a successful conclusion. A modification of this treatment consists in completely excising the aneurism and ligaturing the artery above and below it. Rose treated in this way a case of femoral aneurism in which pulsation recurred after ligature of the external iliac, and Horsley recently excised a popliteal aneurism at University College Hospital after failure of the ligature of the femoral to produce consolidation. In these operations the subsequent dangers of secondary hæmorrhage and profuse suppuration can be avoided only by scrupulous attention to the antiseptic precautions.

In these situations in which amputation is impossible, the Surgeon must attempt the old operation if it be practicable, or leave the patient to inevitable death. Smythe, of New Orleans, as a last resource, laid open a subclavian aneurism, for which he had successfully tied the innominate some years before, but failed to secure the artery, and the patient died. Morris, however, has successfully adopted this proceeding in a case of carotid aneurism after ligature of the common trunk had failed; and Berkeley Hill in a case of axillary aneurism after ligature of the subclavian.

Since the introduction of absorbable ligatures into surgical practice, a return of pulsation has in a few cases been due to a restoration of the lumen of the artery after the disappearance of the ligature. This is recognized by the presence of pulsation in the vessel at the point at which it was tied. These cases belong to a different class from those in which the vessel has been permanently occluded, and require different treatment. The artery may be ligatured again at or near the same spot or at some other point. In a case of this kind that occurred under the care of Christopher Heath in University College Hospital, the femoral was successfully tied in Hunter's canal after ligature of the artery in Scarpa's triangle had failed. The causes of failure of the ligature have already been described (Vol. I., p. 434).

**3. Suppuration and Sloughing of the Sac.**—When, after the ligature of its supplying artery, an aneurism is about to suppurate, instead of diminishing in size, it increases, with heat, pain, pulsation, and some inflammatory discoloration of the skin covering it. This gradually becomes thinned, and at last gives way; the contents of the tumour, mixed with pus, are discharged through the aperture in its wall, in the form of a dark purplish brown or plum-coloured and often fetid fluid, intermixed with masses of soft dark coagula, or of the drier laminated fibrin, which in appearance may not inaptly be compared to portions of raisins or dates. This may be accompanied or followed by the escape of florid arterial blood. The hæmorrhage may occur in a sudden

violent gush, to which the patient may at once succumb at the time of the rupture of the tumour; or it may continue in small quantities, and, after ceasing, recur from time to time, thus gradually exhausting the patient. It is this recurrence of secondary hæmorrhage that constitutes the principal danger after suppuration of an aneurism, which otherwise is not a source of any very serious risk to the patient; about one-fourth only of the cases in which the sac has suppurated have had a fatal termination, and in almost all of these death resulted from hæmorrhage. The patients in a few remaining instances have been carried off by some special accidents, such as the pressure of the sac on the pharynx or œsophagus, or the discharge of the contents of the tumour into the pleura or bronchial tubes. Hæmorrhage is more likely to occur when suppuration takes place a few weeks after the ligature of the artery, than when a longer interval has elapsed. That hæmorrhage does not happen more frequently after suppuration of the sac is very remarkable, and must be owing either to the artery being plugged with coagulum above and below the origin of the aneurism, or, if the artery be pervious, to the closure of the mouth of the sac by coagulum. It is owing to this plugging also, that in many cases the fatal bleeding does not occur at the moment of rupture, but only after a lapse of some days, or even weeks, and then, as a rule, owing to some incautious movement of the patient by which the coagulum is suddenly disturbed. Those cases are most dangerous in which pulsation has returned in the sac after the ligature of the vessel but before the supervention of suppuration; as in these the tumour is so freely supplied with blood that, if it burst, fatal hæmorrhage will with certainty occur.

This accident is more likely to occur in aneurisms of the axilla or groin, than in those of the ham or of the neck. The proximity of the ligature and the necessary interference with the sac in its application, especially in large axillary or inguinal aneurisms, is undoubtedly a frequent cause of it. The large size which these tumours rapidly attain, in consequence of the laxity of their areolar connections, also favours it. Until recently it was believed that the occurrence of simple coagulation, instead of gradual deposit of laminated fibrin, was an important factor in the production of suppuration of the sac; but our late experience of the treatment of aneurism by rapid compression clearly shows that the danger has been greatly exaggerated. In other cases it is probable that the suppuration of the sac is a consequence of pyæmic infection from the wound, corresponding to those cases in which we find the formation of pus occurring in injured or diseased tissues at a distance from the septic wound. Besides this, it has been very justly remarked by Porter, that the excessive handling and frequent examination to which an aneurismal tumour is usually subjected in a hospital may induce inflammation and predispose to suppuration.

The *period* at which suppuration of the sac may occur after the ligature, varies from a few days to as many months. In the majority of instances, it would appear to take place between the third and eighth weeks; later than this it seldom happens, though it may do so after the lapse of several months, as in a case recorded by Astley Cooper, in which a carotid aneurism suppurated at the eighth month.

**Treatment.**—When an aneurism is suppurating, and is on the point of giving way, it will be better to make an incision into it with antiseptic precautions, so as to let out the broken down contents at once. It must

then be treated like an ordinary abscess, with a view to its filling up by granulation: which, however, will necessarily be a slow process, in consequence of the size of the cavity. During the whole of this time a tourniquet should be kept loosely applied upon the artery above the sac, so as to be tightened at any moment if bleeding take place. If hæmorrhage have already supervened, the case is attended with immediate danger. In such a case as this, the first indication is clearly to arrest the flow of blood, so as to save the patient from immediate death. This can best be accomplished by turning out the coagula and plugging the sac with lint or compressed sponge, retained *in situ* by a firm graduated compress and well applied roller. The hæmorrhage having thus been arrested for a time, the Surgeon should consider what steps should be adopted permanently to restrain it. In some cases, indeed, though these are exceptional, the plug and compress may be sufficient to prevent a recurrence of the bleeding; but in general it will not do to trust to these means, unless the anatomical relations of the part be such as to preclude more active measures.

Various plans are open to the Surgeon for the permanent suppression of the bleeding. The sac may be laid open, and an attempt made to ligature that portion of the artery from which the blood issues. But this can scarcely be expected to succeed, as, in the majority of the cases, the coats of the vessel being softened, there would be little prospect of its holding a ligature, even if it were possible to expose it before the patient died of hæmorrhage. Indeed, though this plan has several times been tried, I am not aware that by it the Surgeon has ever succeeded in arresting the bleeding from a suppurating aneurismal sac.

The application of the actual cautery to the bleeding orifice would, I think, hold out a better chance, more particularly if the blood were poured out from a collateral vessel of small size. In this way, Morrison, of Monte Video, succeeded in arresting the bleeding of an aneurism in the groin that had suppurated. Should this means, however, not suffice (and it is the only means that can be applied in many situations, as in the groin and axilla), there is no course left but, in those situations in which it can be done, either to ligature the artery higher up or to amputate. The application of a ligature nearer the centre of the circulation, even though practicable, appears to me to be of very doubtful utility; for the probability is, that the circulation through the limb, embarrassed as it must have been by the first ligature and by the subsequent distension and suppuration of the sac, will be so much interfered with when the artery is tied a second time, that gangrene will result; or else that the collateral circulation, if sufficiently active to maintain the vitality of the limb, will also keep up the hæmorrhage. In these circumstances, the only course left to the Surgeon is amputation of the limb when the aneurism is so situated that it can be removed in this way.

**4. Gangrene of the Limb.**—The general subject of gangrene of a limb, following injury and ligature of the main artery, has already been described (Vol. I., p. 461); and we have at present to consider only those cases in which it occurs after the operation for aneurism.

**Causes.**—If the aneurism have very rapidly attained a large size, it may, by its pressure on the collateral vessels, or on the veins in its vicinity (Fig. 458), produce such an amount of disturbance in the circulation of the limb, preventing the influx of arterial or obstructing the efflux of venous blood,

as to occasion a great liability to the occurrence of gangrene. But perhaps the principal source of danger consists in the *aneurism becoming suddenly and widely diffused*, more particularly in those cases in which the anatomical relations of the collateral vessels are such, as in the ham, that they may readily and uniformly become compressed by the effused blood. In these cases, the additional embarrassment induced in the circulation of the limb by the ligature of its main artery will readily induce gangrene; and hence it is that, in diffuse aneurism of the lower extremity, ligature of the artery is so commonly followed by mortification.

*Loss of blood*, either in consequence of secondary hæmorrhage or in any other way before or after the application of the ligature, is very apt to be followed by gangrene; the more so, if it have been necessary to apply a ligature to a higher point on the trunk of the vessel than had previously been tied. This secondary ligature of a large artery in cases of aneurism has, I believe, invariably been followed by gangrene of the limb, when done in the lower extremity; the interference with the collateral circulation by the second ligature being so great, that the vitality of the part cannot be maintained.

Besides these causes, the occurrence of *erysipelas*, exposure of the limb to *cold*, or to an undue degree of *heat*, or subjecting it to the *compression* of a bandage, may be attended with consequences fatal to its vitality.

The *period of supervention* of gangrene of the limb is usually from the third to the tenth day; it seldom occurs before this period, unless incipient mortification have already set in before the artery was tied. Gangrene usually follows the ligature of the external iliac at an earlier period than that of any other artery. In cases of aneurism, the gangrene is always of the dark and moist variety, owing to its being commonly dependent on pressure upon the large venous trunks by the aneurismal tumour.

**Treatment.**—The general preventive treatment of gangrene following the ligature of the artery for aneurism must be conducted on the same principles as when it arises after the ligature of arteries generally (Vol. I., p. 463). But some special modifications of it are required, so far as the aneurism is concerned. When the gangrene occurs from the pressure of the sac upon the accompanying vein, it has been proposed to lay the tumour open, and to turn out its contents, thus removing the compression. The danger of such a proceeding consists in the probability of the occurrence of hæmorrhage from the opening made into the sac, and in the risk attending suppuration set up in the sac; yet it would appear that, in two cases in which this practice was adopted, no bad results followed. Thus, Lawrence has related a case of diffused aneurism of the popliteal artery, in which this plan was had recourse to with the best results; and Benza has recorded a case of popliteal aneurism in which the same method was adopted in consequence of great œdema and incipient gangrene of the foot; after the extraction of a quantity

Fig. 458.—Popliteal Aneurism compressing the Vein, and thus causing Gangrene of the Limb: a, Artery; b, Vein compressed at d; c, Aneurism.

of flesh-like fibrin from the sac, the patient made an excellent recovery. These cases would certainly justify the Surgeon in adopting such a course when the danger of gangrene is imminent, and dependent on the size and pressure of the tumour. Should, however, the gangrene show any disposition to extend, or should there be hæmorrhage from the sac after it has thus been laid open, the Surgeon must hold himself in readiness to amputate without delay. When gangrene has once fairly set in, there is no reasonable prospect of saving the limb; and the sooner amputation is done the better. The limb must always be removed high up above the sac, and if possible, not only at some distance from the parts that have mortified, but also above the part to which the serous infiltration that precedes mortification has extended. The upper extremity must generally be removed at the shoulder-joint; the lower above the middle of the thigh. In these cases there will generally be a considerable amount of hæmorrhage, and many vessels will require to be tied in the stump, in consequence of the enlargement of the collateral circulation.

**COMPRESSION BY INSTRUMENTS.**—In consequence of the danger and difficulties attending the use of the ligature, Surgeons have endeavoured to treat aneurism by compression. The employment of direct pressure on the aneurism was almost naturally suggested as a means of counteracting its extension by the pressure of the blood from within, and has consequently been applied from a very early period. This plan was first employed by Bourdelot at the close of the seventeenth century; afterwards by Genga, Heister, Guattani and others. These Surgeons made the pressure directly upon the sac; and Guattani and Flajani relate several cures which they effected in this way; but the method was so uncertain in its results, and so dangerous from its tendency to cause inflammation of the sac, that it fell into disuse. The French Surgeons introduced a modification of the pressure plan, by laying open the sac, clearing out its contents, and applying the pressure directly over the opening into the vessel. Deschamps exposed the artery leading to the sac, and compressed this with an instrument which he termed the "*presse-artere*." These barbarous modes of treatment, however, were entirely set aside by the facility and comparative success of the Hunterian operation; and compression in aneurism was rarely practised by Surgeons after the great step made by John Hunter in the treatment of this disease. Yet we find that Hunter himself, Blizard, and Freer attempted, though without success, to cure this disease by pressure on the artery leading to the sac. Pelletan and Dubois appear to have been the first who successfully applied pressure to the artery above the sac, instead of to the aneurism itself; this was in 1810. After this period, various attempts were made methodically to treat aneurisms in this way; but the merit of having introduced the practice of compression in the treatment of aneurism into modern surgery, and of having established the true principles on which it acts, incontestably belongs to the Dublin Surgeons; amongst whom the names of Hutton, Bellingham, Tufnell, and Carte deserve especial mention.

**Principle of Compression.**—In the early trials of the cure of aneurism by compressing the artery on the cardiac side of the tumour, the Surgeons who employed this method acted on an erroneous theory; and, the principle not being understood, the practice was bad. It was supposed to be necessary, in order that a cure might take place, that the *whole* flow of blood through the

artery should be arrested ; that inflammation of the vessel at the point compressed should be set up ; and that the consolidation of the aneurism depended upon the obstruction of the vessel consequent upon this inflammation. This led to the employment of such forcible compression, with the view of exciting inflammation in the artery, that the patient could seldom bear it for a sufficient length of time to effect a cure ; sloughing of the skin commonly resulted from the severity of the pressure to which it was subjected. The Dublin Surgeons however pointed out the error of this doctrine, and laid down as the principle of the practice, that, in the majority of cases, the cure is brought about when the artery is compressed, in precisely the same way as when it occurs spontaneously, or when the Hunterian operation is performed—viz., by the deposit of stratified fibrin, and by the consequent consolidation of the aneurism (Fig. 459), aided by the contraction of the walls of the sac. It was further shown that, as in the case of ligature of the vessel, it was not necessary that the whole of the circulation through the aneurism should be permanently arrested, but merely that it should be lessened to such an extent as to induce the deposit of laminated fibrin in the sac, and that, if the pressure were properly conducted, the artery was in no way injured or occluded at the part compressed. The recognition of the true principles on which compression of the artery leading to the sac cures the aneurism has led to important results ; for as the severe pressure that was formerly considered necessary is now known not only to be unnecessary, but to be absolutely injurious, no amount of compression is exercised beyond what is requisite to moderate the flow of blood into the sac ; no attempt being made to compress the artery so severely as to lead to its obliteration by inflammation.

Fig. 459.—Sac of Aneurism cured by Compression : Deposit of Laminated Fibrin.

But, although, where the pressure is moderate or the anastomosing circulation free, the consolidation of the contents of the sac takes place in the way that has just been described, it would be an error to suppose that this is the process by which the aneurism becomes cured in all cases in which recourse is had to compression. There can be no doubt that in some cases, in which consolidation has taken place in a few hours after the employment of pressure, coagulation of the contents of the sac has suddenly occurred ; and this sudden coagulation, which at one time was dreaded by Surgeons, has been found by increased experience to be in the highest degree advantageous, as leading to a more rapid cure.

In the tubular form of aneurism, which is far less frequent than the sacculated in the extremities, the cure appears to take place, if it occurs at all, rather by the gradual contraction of the partially emptied sac than either by the slow deposit of laminated fibrin, or by the rapid and almost sudden coagulation of its contents. The sac gradually shrinks, and shreds of fibrin only are found adherent to its sides. But although I believe that the condition of the aneurism, whether sacculated or tubular, has a considerable influence upon the mode in which compression acts in effecting a cure, and also upon the time that is occupied in the treatment, this being much shorter in the sacculated than in the tubular form of the disease ; yet there can be no doubt that this

is materially influenced also by two other circumstances—viz., the condition of the blood within the sac, and the completeness of the compression.

When the sac is filled with fluid blood, and the compression is not uninterruptedly complete, the sac appears to empty itself to a considerable extent, and eventually to consolidate by the deposit of laminated fibrin. But, if the sac already contain some solidified layers, and the compression be continuous and complete, the coagulation of the remaining fluid part of its blood is apt to take place rather suddenly. But in all cases the contraction of the sac, consequent upon the arrest or restraint of the current of blood into it, is an important element in the cure. There is a preparation in the Museum of University College (Fig. 460), illustrative of this mode of cure.

It would thus appear that the cure of an aneurism may take place in three different ways: 1, by the slow deposit of laminated fibrin: 2, by rapid coagulation of the contents of the sac: 3, by contraction of the sac. The particular mode of cure will depend upon the completeness of the compression and the more or less perfect arrest of the blood in the sac, the coagulability of that blood, and the shape of the aneurism.

Fig. 460.—Sac of Tubular Aneurism cured by Compression: Contraction of Sac, and Irregular Deposit of Fibrin.

**Circumstances Influencing Success.**—The success of compression depends greatly upon a scrupulous attention to a number of minor circumstances, which, though each be trifling in itself, become of importance when taken together. During the whole time, also, the patient's general health should be attended to in accordance with those principles that have already been laid down in speaking of the constitutional treatment of the disease. The irritability of the system must also be lessened, if necessary, by the use of opiates or of chloral; and the patient should be put into a comfortable bed, with firm and

well-secured pillows and mattresses, so that his position may not be changed. As it is principally in aneurism of the lower extremity that compression can be employed, we shall proceed to describe the method of its application here.

**Application of the Compressor.**—The thigh should, if necessary, be shaved. The skin should then be powdered, and the limb bandaged with a soft roller; a pad being laid on the tumour. Pillows must then be comfortably arranged under it, the knee being semi-flexed. Much of the success of the treatment will depend upon the kind of instrument used. The ordinary horse-shoe, or Signorini's tourniquet, was the one first employed, and this will, in many cases, answer the purpose perfectly well; but, as it is somewhat difficult to regulate the pressure with this instrument, and as it is not unfrequently exercised too powerfully, it has generally given place at the present day to the very ingenious apparatus of Carte, which, as it substitutes an elastic force derived from vulcanized india-rubber bands for the unyielding pressure of the screw, accommodates itself better to the limb, and is less likely to produce injurious compression. This instrument as well as the other contrivances which have at various times been invented for the treatment of aneurism by compression, are described by Bellingham and Tufnell, in their

works on this subject, to which I must refer for a fuller account than I can here give.

In applying the compressor, especial care must be taken that it is well padded in every part, so as not to gall the skin. In some of the early cases in which I saw compression employed in London by means of the horse-shoe

Fig. 461. — Compressor for the Middle of the Thigh.

Fig. 462. — Compressor for the Groin.

tourniquet, much inconvenience resulted from want of attention to this point. The tendency to irritation of the skin is much lessened by powdering the limb, and the removal of the hairs by shaving. In order to keep up continuous pressure, and at the same time to prevent injury to the skin, it is of very great consequence that two instruments should be used at the same time, so that when one is screwed down the other may be loose; these instruments need not be placed close together. If the aneurism be in the ham, it will be sufficient for one (Fig. 462) to be applied to the groin, whilst the other (Fig. 461) is put upon the middle of the thigh (Fig. 463). In using the instrument, the great point is to control the circulation with the minimum

Fig. 463. — Two Compressors applied for Femoro-popliteal Aneurism.

of pressure. In order to do this, the first instrument should be screwed down so that all pulsation ceases in the tumour, but still not so tightly as completely to arrest all the flow of blood through it. As the pressure exercised by this becomes painful, the second compressor must be screwed tight, and then the first may be slackened. In this way an alternation of pressure can be kept

up without much pain or inconvenience. If possible, the patient should be taught how to manage the instrument himself, and will often find occupation and amusement in doing so. If, however, it excite much pain or irritation, it may be necessary to give opiates or chloral hydrate. The pressure should, if possible, be continued during sleep; but if it prevent the patient from taking his natural rest, the suggestion made by Tufnell, of unscrewing the instrument slightly, and, when the patient is asleep, gently tightening it again without awakening him, may advantageously be adopted; it is indeed surprising how very little unscrewing will relieve the pain of the compression. A large cradle should be placed over the patient's body, so that the weight of the bed-clothes may be taken off the apparatus, and that the patient may manage it without risk of disturbance. Should there still be much uneasiness, the instrument might be taken off for a few hours, and compression kept up in an intermittent manner. Even in such circumstances as these, consolidation of the sac may ensue.

Fig. 464.—P. H. Watson's Weight Compressor. The circular dotted line shows the position of the fluid.

The employment of a *weight* may sometimes advantageously be substituted for the clamp, and often occasions less distress to the patient. For this purpose the apparatus shown in Fig. 464 will be found very useful. A very simple instrument is Tufnell's compressor, represented in Figs. 465, 466. It consists of little more than a tross-spring, with a pad to compress the artery, and straps to fix it in its place, and increase, by being tightened, the force of the compression.

**Compression under Anæsthetics.**—In some cases, in which, from the situation of the aneurism, deep and severe pressure is required to control the circulation, the pain becomes so unendurable that the patient cannot submit to the treatment sufficiently long for a good effect to be produced. Opium or chloral hydrate may then possibly enable him to bear the pressure, but more complete narcotism is often necessary. In these circumstances chloroform becomes a most useful adjunct; and by prolonging the anæsthesia for several

hours, the amount and duration of pressure requisite to effect a rapid cure may be maintained. In this way W. Murray of Newcastle—to whom is due the merit of first employing prolonged anæsthesia as an adjunct to compression—cured an aneurism of the abdominal aorta by keeping up pressure on that vessel for five hours under chloroform. Heath of Newcastle cured an aneurism of the external iliac by compressing the abdominal aorta for seven hours under chloroform; Mapother of Dublin treated an ilio-femoral aneurism successfully by compressing the common iliac artery for four and a half hours; and Lawson cured an inguinal aneurism by pressure on the abdominal aorta for four hours. In two cases of popliteal aneurism I kept up completely obstructing pressure on the common femoral artery, under chloroform, for twelve hours. By these means the only serious objection to the employment of pressure, and the most common cause of its failure, may be prevented; and it is clear that, under chloroform, pressure may be applied to arteries,

Fig. 465.—Tufnell's Compressor.

such as the subclavian and carotid, on which it could not otherwise be used.

The **Effects upon the aneurism** vary considerably. In some cases it

Fig. 466.—Tufnell's Compressor applied.

rapidly and suddenly solidifies ; more commonly, however, this is a gradual process, the aneurism becoming more painful and more solid, with less pulsation and bruit. As the solidification takes place, there is usually some

restlessness, a feeling of general uneasiness, and of constitutional disturbance, which is best quieted by opiates. As the pressure is continued, and the tumour begins to harden, the anastomosing vessels enlarge, with a good deal of burning pain in the limb generally, and arterial pulsation in situations where usually none is naturally felt. The abnormal pulsation is always found to occur in much the same situations, the same vessels appearing to undergo dilatation. Thus I have had more than one opportunity of confirming Tufnell's remark that in the treatment of popliteal aneurism by compression, three arteries will be found to be enlarged, one of which passes over the centre of the tumour, another over the head of the fibula, and the third along the inner edge of the patella. Tufnell also states that the severe burning pain which is felt in these cases is owing to the artery accompanying the communicans peronei nerve being enlarged. After complete solidification of the tumour has taken place, the compression ought to be continued for at least forty-eight hours, so as to guard against a relapse.

The **Duration of the Treatment** varies very greatly. In some cases, as above stated, the tumour has become solidified in a few hours or in two or three days. In other instances, the treatment has required to be protracted for more than three months before a cure has resulted. In 26 cases of femoral or popliteal aneurism cured by compression in the London hospitals, the average time, according to Hutchinson, was nineteen days. Barwell has collected from American, British, and Continental journals all the recorded cases of popliteal aneurism cured by compression in the ten years 1870 to 1879 inclusive, and he gives the following statistics of the duration of the treatment. For instrumental compression the longest period was 7 weeks, the shortest 24 hours, the mean of 19 cases in which the time was recorded, 12 days; for digital compression, the longest period was 21 days, the shortest  $4\frac{1}{2}$  hours, and the mean of 13 cases  $5\frac{1}{2}$  days; for combined instrumental and digital compression the longest period was six months, the shortest 44 hours, and the mean of 12 cases  $44\frac{1}{2}$  days. Much, of course, will depend, in this respect, on the constitution of the patient, and on the condition of the tumour; those circumstances which are most favourable to the spontaneous cure of the aneurism will also influence the rapidity of the cure by compression. There are, undoubtedly, certain conditions of the blood in which it is little disposed to coagulate, and in these cases the duration of the treatment will necessarily be prolonged. So also, when the aneurism is tubular, we must expect that the blood which passes freely through it in the direct current of the circulation will be slower in depositing layers of fibrin than when the disease is sacculated, and thus contains a residuum of blood that is not so directly influenced by the current through the sac. In the early days of this treatment there was an indisposition on the part of Surgeons to apply compression very firmly, and a longer time was expended over it than is now generally the case; and the example set by Murray, with regard to abdominal aneurism, has been followed with success in respect to the femoral, popliteal, and other forms of the disease, the compressor being screwed down tight on the artery so as completely to arrest for the time all circulation through the sac, the patient being kept under chloroform, and the cure effected in a few hours.

**Applicability.**—Of the great value of compression in the treatment of aneurism, there can be no doubt; more especially when the tumour is situated

in the arteries of the lower extremity below the middle of the thigh. In aneurism occurring in the vicinity of the trunk, as in the iliac, the carotid, subclavian, and axillary arteries, it is generally not so applicable; although, as we have already seen, aneurisms in the groin have been cured by compression of the abdominal aorta, or of the iliac artery. Spontaneous aneurism is extremely rare in the upper extremity; and, as the traumatic forms of the disease which occur here generally require that the sac should be laid open, it is seldom found necessary to have recourse to it in this part of the body, though it may be and has been successfully applied to the brachial artery.

The great question with regard to compression appears, after all, to be whether it possesses any special advantages over the ligature, in the treatment of those aneurisms in which its employment is practicable. The principal objections that have been urged against it are, that its employment is more painful and tedious than the use of the ligature; and that those cases that are unpromising to the ligature, or that require amputation rather than deligation of the artery, are equally unfavourable to compression, and cannot be saved by its employment.

To these objections it may with justice be answered that the pain attendant on the employment of compression depends very greatly upon the skill and care with which the apparatus is managed, as well as upon the kind of instrument used, being certainly much diminished when Carte's elastic compressor is employed; and that, as has already been shown, the pain may be overcome by the use of anæsthetics. With regard to the relative tediousness of the treatment under the two plans, it would appear that in reality there is but little difference; for although some cases, in which compression is used, are prolonged over a considerable space of time, yet they do not occupy more than is often consumed when accidents of various kinds follow the use of the ligature; and it not unfrequently happens after compression, but can never occur after the employment of the ligature, that the patient is cured of his disease in a few hours or days. Taking the averages, however, we find that in the Dublin cases the treatment lasted twenty-five days, and in the London cases collected by Hutchinson but nineteen, and this is not very different from what formerly happened when silk ligatures were applied so as to cut through the artery and be finally withdrawn from the wound; for of fifty-four cases recorded by Crisp in which the femoral artery was tied, the average time for separation of the ligature was eighteen days, and if to this a week more were added for the closure of the wound, and for the treatment of the various accidents that often accompanied and followed ligature, we should probably be within the mark, and yet only bring the duration of the treatment by the two methods to the same level. In the present day, however, ligatures which are either absorbable, or are intended to become enclosed in the wound, are almost universally employed; and, as with the improved methods of treating wounds, union by first intention, or within ten days, is the rule, the treatment by ligature has come to be the more speedy mode of cure.

Surgeons will, however, eventually be guided in their estimate of the value of these two plans, not so much by the question of submitting their patients to a slightly more painful or tedious treatment, as by the comparative risk to life entailed by one or other method. Upon this point statistics have yet to be collected; partly because the unsuccessful cases of ligature have not been so

commonly published as the successful ones, and partly because sufficient time has hardly yet elapsed since the general adoption of absorbable ligatures and antiseptic treatment to enable us to form a correct conclusion as to the diminution in the death-rate that may be effected by their use. Statistics published by Bellingham in 1851 (*Med.-Chir. Trans.*, Vol. XXXIV.), and by Holmes in his well known *Lectures on the Treatment of Aneurism* in 1874, showed clearly that though the treatment of popliteal aneurism by compression is attended with scarcely any direct danger to the patient, it very frequently fails to cure the disease. On the other hand, ligature of the femoral artery is far more certain as a means of cure though necessarily attended with more direct danger from the operation, a danger which the statistics show has progressively decreased during the last thirty years. The latest statistics on this subject are those published in 1883 by Barwell in his admirable article on Aneurism in the *International Encyclopædia of Surgery*. He has there collected 148 cases of popliteal aneurism treated by compression between 1870 and 1880. Of these, 68 were successful, while 80 ended in failure. Of the unsuccessful cases, 57 submitted to ligature, 2 went away unrelieved, 4 suffered amputation, and 6 died. Of the 6 deaths, 2 occurred from rupture of the sac, 2 from "thrombosis," 1 from gangrene, and in one the cause was not stated. During the same period, 67 cases of ligature occurred in six of the chief London hospitals. Of these, 10 died. If these are further subdivided, it will be found that out of 32 cases which occurred in the first half of the decade, 7 died and 2 underwent subsequent amputation; while from 1875 to 1879 inclusive, 35 cases occurred, with 3 deaths and no amputations. Whether this great improvement is merely accidental, or is the result of the improvement in the material used as the ligature and in the treatment of the wound, remains to be seen, but there is great reason to believe that the latter is the true explanation.

If compression fail, ligature may be applied in some cases with a better prospect of success than if compression had not previously been tried, that treatment having caused the collateral circulation to enlarge, and thus lessened the tendency to gangrene. If, however, we take the general average of those cases that have been submitted to ligature after the failure of compression, we shall find that the result is not so satisfactory as when the ligature has been employed as the primary method of treatment. Thus I find that, out of 40 cases in which the ligature was employed after compression had failed, there were 16 deaths. This is probably not so much due to the previous employment of compression, as to the same causes interfering with the consolidation of the tumour after the ligature that had prevented the success of the compression treatment. With regard to the facility of ligaturing an artery such as the femoral, after compression has been tried and has failed, it must be admitted that the difficulties are increased. The sheath of the vessels is apt to become thickened, and the artery and vein are perhaps less easily separable than when pressure has not previously been employed.

It should also not be forgotten that in some cases, as when aneurism is complicated with heart disease, or occurs in a very broken and unhealthy constitution, in which the operation necessary for ligature would be scarcely or not at all admissible, compression may safely be employed.

After carefully considering the relative merits of the two plans of treatment,

I think we may conclude that, though in some few cases neither ligature nor compression can be adopted, and amputation is the sole resource, yet in others compression can be employed when it would not be safe to have recourse to the ligature; and that, in all ordinary cases of femoral and popliteal aneurism especially, compression should be preferred to the ligature, inasmuch as it is not a more tedious method of cure, while it is infinitely safer. At the same time, it must not be forgotten that its success depends very greatly on the continuous care bestowed upon the case during the progress of the treatment.

**DIGITAL COMPRESSION.**—Shortly after the introduction of the treatment of aneurism by instrumental compression, the fingers were used as an adjunct to the mechanical means in use. Thus Greatrex, in 1845, directed a patient to keep up compression by means of the fingers, where the tourniquet had been used, and required to be loosened. In 1846 Vanzetti, then Professor of Surgery at Charkoff, tried, but unsuccessfully, to cure a large popliteal aneurism by compression of the femoral with the fingers only, continued for two days. It was not until seven years later, when Professor at Padua, that Vanzetti had an opportunity of putting this method successfully in practice, and to establish it as a distinct means of curing aneurisms. But although this merit is undoubtedly due to Vanzetti, we must credit Knight of Newhaven (U. S. A.) with the first successful case—he having, in 1848, cured a very large popliteal aneurism by digital compression, maintained for forty hours.

In this plan of treating aneurisms, no apparatus of any kind is used; but the circulation through the artery leading to the tumour is controlled by the pressure of the finger. In order to carry it out there must be relays of assistants, each of whom compresses the vessel for about ten minutes at a time. The pressure should be applied in the way that is represented in Fig. 19, Vol. I., p. 53. The fatigue may be very materially lessened by placing a 6 or 8 lb. weight on the compressing finger. With such aid each assistant may be able to keep up the pressure for half an hour at a time. As soon as his fingers become fatigued, but before he relaxes the pressure, another assistant compresses the vessel; and thus the circulation through it may be uninterruptedly controlled. In this way aneurisms of the popliteal artery, in the orbit, at the bend of the arm, and in the groin, have been successfully treated—the tumour having in some instances become consolidated in a few hours. The effect of digital compression and the rapidity of cure would be increased by the application of direct pressure to the tumour, and by the previous employment of proper constitutional means; it might in some cases be very advantageously conjoined with the treatment by flexion. But its chief advantages seem to be, that it is applicable to arteries, as those at the root of the neck, to which it might be difficult to apply any kind of compressor, and that it can be employed when no apparatus is obtainable.

**ESMARCH'S ELASTIC BANDAGE** has been used with a certain amount of success in the treatment of external aneurisms. It was first employed in these cases by Sir Walter Reid, R.N. in 1875. Pearce Gould, who has carefully investigated this method of treatment, has collected details of 72 cases in which it has been employed. Of these he finds that 35 were cured, in 30 the treatment was unsuccessful, in 5 death resulted, and in the remaining 2 the result was doubtful.

The treatment has been applied chiefly to aneurisms of the popliteal artery, but in a few cases it has been successfully employed in other situations. The objects in view are, first, to empty the whole limb of blood as far as possible, with the exception of the sac and the part of the artery in immediate connexion with it; secondly, to keep the blood distending the sac at perfect rest until coagulation has taken place; and thirdly, to protect the soft clot thus formed from the influence of the arterial current until it has become sufficiently tough and solid to resist it, by compression of the trunk leading to the aneurism. In the case of a popliteal aneurism, the treatment is thus carried out. The elastic bandage is first applied from the toes to the ham with sufficient force to render the limb bloodless; it is then carried loosely over the tumour, so as not to empty the sac, and again applied firmly as high as the middle of the thigh; the elastic tourniquet is then put on with sufficient force to arrest the circulation completely. The bandage is better left on till the tourniquet is removed. The average time required for the application of the bandage is one hour and a half. The time during which the limb may be kept bloodless with impunity is uncertain. Heath kept the tourniquet on in one case for three hours, and in another for three hours and a quarter, without evil consequences; and Barwell in one case retained it for five hours. The limb must be wrapt in cotton-wool, and, if necessary, warm bottles, at a temperature of about 100° F., may be applied. The pressure causes severe pain, which may require the use of hypodermic injections of morphia; but if the treatment is continued for more than one hour, it is usually necessary to administer an anæsthetic. Before the bandage is removed a Carte's compressor may be applied, or arrangements made for keeping up digital compression, and this must be maintained for from two to six hours, even if all pulsation has ceased when the tourniquet is taken off.

The mode by which the elastic bandage effects a cure is by causing stasis of the blood in the aneurism and the adjoining part of the artery. This stagnant blood coagulates, the clot being formed first in the aneurismal sac, and then spreading to the artery. Gould is of opinion that the permanent cure of the aneurism is effected chiefly by means of the portion of coagulum extending into the artery. This being in contact with the comparatively healthy walls of the vessel undergoes the changes described in the chapter on wounds of arteries (Vol. I., p. 415); the vessel is thus permanently occluded. The clot in the aneurism, on the other hand, being in contact with the unhealthy walls of the sac, or with layers of laminated fibrin, tends to become friable, and to yield before the pressure of the blood, unless protected by the thrombus in the artery. If, however, the vessel be safely occluded, the sac and its contents gradually shrivel and are absorbed. Failure has in some cases apparently been due to the bandage having been applied too tightly over the tumour, so that the sac was but partly filled by the coagulum. In other cases it may have been due to a want of coagulability of the blood, and in order to avoid the possibility of this it is well to submit the patient to a course of medical treatment and diet (p. 118) before applying the bandage.

If, on removal of the bandage, there is still distinct pulsation to be felt, although the tumour seems partially consolidated, a cure may often be effected by digital or instrumental compression in a few hours.

The chief danger to be apprehended seems to be gangrene, which has

occurred in more than one case. It appears to have been due to thrombosis taking place in the vein, and possibly also in the capillaries of the parts in the neighbourhood of the aneurism from which the blood had not been expelled. This, with the simultaneous occlusion of the artery, would offer an amount of obstruction to the circulation which would almost certainly end in gangrene. The only means of avoiding it seems to be by carrying the bandage lightly over the tumour, whereby the veins may be emptied while the fulness of the sac is not interfered with. The expulsion of so large an amount of blood from the limb necessarily raises the arterial tension in the rest of the body; consequently the use of the elastic bandage is not to be recommended when the patient is affected with an internal aneurism which might rupture under the strain. For the same reason it should be avoided when there is a suspicion of fatty heart.

The elastic bandage is most likely to succeed in effecting a cure in aneurisms that are beginning to undergo consolidation. It is of little use in aneurisms that are large and rapidly increasing, with thin walls and fluid contents.

**FLEXION.**—The treatment of aneurism by flexion of the contiguous joint is a method that is rarely applicable to any other form of the disease than the popliteal. The history of this plan of treating aneurisms is interesting, as an illustration of the gradual steps by which Surgery usually arrives at its ultimate results. It had been long known to Surgeons that the pulse at the wrist might be arrested by the forcible flexion of the forearm on the arm; and Malgaigne and Richet had recommended this means for the arrest of hæmorrhage from the brachial artery and the arteries of the forearm when wounded. Fleury—a distinguished French naval Surgeon—having succeeded in curing a wound of the brachial artery by forced flexion of the elbow, aided by direct compression, and one of the radial by flexion of the wrist, published in 1846 a memoir in which he stated, as a conclusion from his observations, that any aneurism of the forearm or leg might be treated by means of flexion of the limb in which it was situated. To A. Thierry is due the honour of having been the first to cure a traumatic aneurism of the bend of the arm by flexion of the limb. This was in 1852 (Richet, *Dict. de Méd. et de Chirurgie*, Vol. II., p. 338). In 1857, Mannoïr of Geneva applied the flexion treatment to a large aneurism of the ham. Forced flexion could not be borne on account of the pain it occasioned, and the patient was therefore allowed to walk on crutches with the leg bent, and supported in a kind of a stirrup attached to the opposite shoulder. In less than three weeks the cure was effected, which Mannoïr found a year afterwards to be permanent. In 1858, Hart applied this method of treatment successfully in a case of popliteal aneurism, and to him is due the merit of having first introduced it into this country.

Flexion is necessarily applicable only to arteries situated in the bend of joints, as the elbow or ham, in which the circulation can be directly controlled by bending the limb, or in traumatic aneurisms in the limbs below these joints, in which the flow of blood through the feeding artery can be stopped in the same way. Its application is therefore somewhat limited, and its use is still further restricted by the pain and insupportable annoyance occasioned in many cases by forced flexion of the limb, necessitating, as in Mannoïr's case, a relaxation of the method, which, however, was still effective in curing the aneurism.

Nothing can be simpler than the details of this plan. It consists, in the lower limb, in applying a bandage as high as the knee and then gradually flexing the leg upon the thigh, so that the heel is brought up towards the buttock, where it is retained by a strap or bandage. The patient is at the same time confined to bed, and put under proper constitutional treatment. By this means, the popliteal artery being bent at an acute angle, the circulation through it is nearly, if not completely, arrested; and the obstacle to the flow of blood is still further increased by the compression of the tumour between the posterior flat surface of the femur and the upper part of the calf. In this way the aneurism is most favourably situated for the consolidation of its contents, which, in the recorded cases, has often taken place at an early period.

The principle on which the cure is effected in these cases appears to be, that by flexion the artery leading to and from the sac, and the aneurism itself, are so compressed that retardation of the circulation ensues, and deposition of laminated fibrin takes place in the usual way. The compression by flexion is most likely to be successful in those cases in which the aneurism is small, situated low in the popliteal space, and in a young or middle-aged subject, who can bear the continued flexion without much inconvenience. When flexion is not sufficient of itself to cure an aneurism, it may very advantageously be had recourse to in addition to other methods of treatment, more especially that by digital compression.

The statistics of the treatment by flexion require to be carried down to the present time. Those published by Fischer in 1870 comprised 57 cases. Of these 28 were cured—20 being by flexion alone; and in 29 the method failed.

The various methods of employing compression, viz., by clamps, by weight, by flexion, and by the finger, may often be advantageously combined in the same case. When the patient tires of one, another may be substituted for it; and thus the good effects are continuously kept up with less fatigue and irritation than would otherwise be experienced. So also various modifications of these different methods may be practised to suit the requirements of any particular case. But for these no special directions can be given; the ingenuity of the Surgeon must supply the want in each case.

**MANIPULATION.**—In 1857 Fergusson proposed to treat some aneurisms by a procedure which he termed *manipulation*. This consists in squeezing the aneurismal tumour in such a way as to detach a portion of the coagulum within it, which, being carried on with the current of blood into the distal end of the artery, obstructs this; and thus, by impeding the circulation through the sac, may lead to its consolidation. It has also been suggested by Oliver Pemberton that the alteration of the relations of the laminated fibrin in the cavity of the aneurism may bring about a further deposition of fibrin on the displaced laminae. This procedure can scarcely be considered, nor is it intended to be, of very general application. To aneurisms, however, that are not amenable to ordinary surgical treatment, and that must necessarily prove fatal if left alone—as in those situated at the root of the neck, more particularly of the subclavian artery—it might possibly be advantageously applied. It is scarcely necessary, however, to point out the obvious danger of rupture of the sac, or of the diffusion of the aneurism from the weakening of its walls by the separation of the coagulum, to make Surgeons use due caution in carrying out this

method of treatment. There is another danger also especially attendant on this procedure, when applied to aneurisms about the neck: viz., that the detached coagulum may be carried by the circulation into the cerebral arteries, and by obstructing them occasion the same kind of cerebral disturbance that occurs when these vessels become occluded by fibrinous plugs—embola. That this danger is a real and a great one, is evident from the fact that, in some cases in which manipulation of subclavian and carotid aneurisms has been tried, the patient has been suddenly seized with syncope and hemiplegia. Teale has successfully conjoined manipulation with compression in a case of popliteal aneurism, in which the pressure on the artery was slow in consolidating the tumour; the detachment of a portion of the coagulum almost at once led to the consolidation of the tumour. Somewhat analogous to this method is one recommended in 1842 by Blake, who proposed, by the introduction of a cataract-needle into the sac, to detach some of the laminated fibrin, which might then be washed against the aperture of the exit and occlude it.

**GALVANO-PUNCTURE.**—The attempt to bring about the consolidation of an aneurismal sac by the employment of electricity is of comparatively recent date. It appears to have been first practised by B. Phillips, about the year 1832. Little attention, however, was given to the mode of treatment until a few years back, when it was revived by some of the French and Italian Surgeons, especially Pétrequin, Burci, and Ciniselli. The object aimed at by this operation is the production of coagulation in the aneurismal sac by decomposition of the blood contained in it by means of the galvanic current. When two needles connected with the poles of a galvanic battery are introduced into a mass of fluid blood, a firm solid coagulum is rapidly formed round that connected with the positive pole, while at the same time a large soft, spongy clot mixed with bubbles of gas is seen at the negative needle, and a dark, tar-like fluid also makes its appearance. If the needle used be made of steel, further changes occur at the positive pole due to the production of salts of iron with the acids liberated from the blood. These changes are spoken of as secondary electrolysis. The clot formed by electrolysis is, therefore, not composed simply of the fibrin of the blood, but also contains a large proportion of albumen coagulated by the chemical action of the current, and must be looked upon as a foreign body around which it is hoped that ordinary coagulation will occur.

The operation of galvano-puncture is best performed as follows. Two steel needles, well insulated with vulcanite or gum elastic, are inserted into the sac of the aneurism and connected with the opposite poles of the battery. The needles should be about one inch apart, parallel to each other, and so inserted that no part of the uninsulated portion of the needle shall touch the sac. The best battery for the purpose is one of the ordinary medical batteries with small Leclanché cells, of which from ten to twenty may be used for a time varying from twenty minutes to half an hour or more, according to the effect produced. If the tumour be sufficiently near the surface to be clearly observed, as has been the case in several of the aneurisms in which this treatment has been employed, it will be seen to become more tense and firm, and the expansile nature of the pulsation will become diminished as the operation progresses. Sometimes bubbles of gas escape by the side of the negative needle, and a little thick brown fluid oozes up. Occasionally the tumour has been found to swell and become resonant on percussion. When a distinct

effect has been produced the needles may be withdrawn, and the small punctures closed with lint and collodion. The negative needle will be found unaltered, while the positive will be corroded in direct proportion to the amount of electrolytic action that has taken place. In order to prevent this corrosion of the positive needle, it has been suggested by John Duncan of Edinburgh that platinum should be used instead of steel. There is no evidence, however, that the salts of iron produced give rise to any particular danger; in fact, it is probable that they aid considerably in the formation of the firm coagulum surrounding the needle. The battery used in the operation is of considerable importance. It has been pointed out by Ciniselli that a current of high tension and somewhat low intensity is less likely to cause the production of undue heat during the operation, and is consequently less prone to lead to inflammation and suppuration of the sac. A battery composed of a large number of small elements is therefore superior to one of a few large elements. Some operators, and especially Bastian, have advocated the introduction of the positive pole only, the negative being attached to a sponge or metal plate laid on the skin near the aneurism. The only objection to this mode of treatment is the excessively small effect produced. The electrolytic action which takes place is directly proportional to the intensity of the current; and by the inclusion of a considerable mass of the tissues of the patient in the circuit, the resistance is so greatly increased that electrolysis is reduced to a scarcely appreciable amount, the positive needle appearing almost unchanged after the operation. Others, again, have introduced the negative needle only; as, however, the coagulum formed at the negative pole is soft and frothy, but little good can be expected from this mode of operating. Julius Althaus, who has superintended the operation in five cases, is strongly of opinion that "the most effective application of the current is that where both poles are inserted into the sac." Ciniselli operated in this way, and Duncan and Fraser, to whom we are indebted for many important observations on galvano-puncture and for the invention of reliable insulated needles, support the same view. The operation is accompanied by but little pain, and it is only occasionally that chloroform is needed. The effect of a single operation is seldom sufficient to cause any marked improvement in the condition of the patient, and it usually requires to be repeated several times.

The clot formed as the result of galvano-puncture is somewhat soft and yielding, and unless supported by a moderately firm sac soon flattens out or disappears, and the condition of the aneurism becomes much the same as it was before the operation. Little more than the most transient relief can for this reason be expected in many cases; and whenever the aneurism has become diffused, the operation can only be productive of mischief by hastening the inflammatory changes occurring round the sac. It might be supposed that so soft a clot would readily break up, and that there would consequently be great danger of embolism; but no such accident has happened in any of the recorded cases. Suppuration of the sac has occasionally taken place, but its occurrence has been much less frequent since the principles of the operation have been more fully understood. The formation of sloughs round the needle punctures, and consequent hemorrhage, have not been noticed except when the needles have been imperfectly insulated. In fact, it may be said that in almost every case, even when the operation has failed to give relief, it has at any rate done no harm.

The general results of the published cases have not been unfavourable when we consider the hopeless nature of the cases in which the operation has been performed. Ciniselli asserts that of 13 cases of aneurism of the aorta treated by his method, five were cured, and no evil consequences followed in any case. Of the same number which have been operated on in this country during the last few years, none have been cured, but at least six experienced more or less relief; and in almost all, it may be said, the operation aimed only at relief, the disease being too advanced to warrant any hope of cure. About sixty other cases of aneurism of various arteries have been collected by Ciniselli as having been operated on before 1868; but in these the methods used were so imperfect, that they cannot be fairly considered as bearing upon the question at the present time.

When we compare galvano-puncture with ligature or compression in the treatment of external aneurism, it is, I think, impossible to hesitate for a moment in giving a decided preference to the latter modes of treatment, as the results that have hitherto been obtained from the former are not such as would justify a prudent Surgeon in submitting his patient to an operation of this kind, when he possesses such certain and comparatively safe modes of treatment as deligation or compression. In internal aneurisms, or in those cases in which the disease is so situated at the root of the neck that the artery can neither be ligatured with safety nor compressed, galvano-puncture is certainly justifiable, especially when conjoined with proper medical treatment, as we have ample proof that with the knowledge and means now at our disposal we can perform the operation with scarcely any danger to the patient, and in favourable cases with some hope of relief. Much will depend upon the selection of the case. Ciniselli has pointed out that the conditions favourable to success, are that the aneurism shall be sacculated and opening into the vessel by a narrow mouth, of slow growth and of medium size, and, when thoracic, situated entirely within the thorax, and that it shall not in any serious way have interfered with the general health of the patient. These conditions seldom occur; and when they are absent, the most that can be hoped for is temporary arrest of the progress of the disease and some relief to the patient's sufferings.

**INJECTION WITH PERCHLORIDE OF IRON.**—The injection of aneurismal sacs with a solution of perchloride of iron has also been practised, with the view of coagulating their contents, but such treatment is attended with considerable risk of embolism and may give rise to inflammation and suppuration. Its employment would, therefore, be suggested only in cases in which either from the situation of the aneurism, or its complication with extensive disease of the arterial system, neither proximal nor distal ligature nor compression is applicable, and in these probably the introduction of foreign bodies into the sac or galvano-puncture would be less dangerous and equally likely to be successful. Gamgee has suggested the injection of fibrin-ferment into the sac, while the circulation through it is arrested by pressure, as a means of determining coagulation. This has been once practised by Southam in a case of iliac aneurism, but without success.

**HYPODERMIC INJECTION OF ERGOTIN.**—Langenbeck advocated the hypodermic use of a watery extract of ergot in cases of aneurism, under the impression that it might act on the muscular fibres scattered over the sac of the aneurism in the same way as it acts on the muscular fibres of the uterus, and

by causing contraction might gradually diminish the size of the aneurism, if not cure it. He seems to have tried it in only two cases. One was an aneurism in the supraclavicular region (exact nature not mentioned), which had previously been treated with moxas, and almost cured. The symptoms having returned, hypodermic injections of ergot were tried. The quantity injected varied from about  $\frac{1}{2}$  grain to 3 grains of Bonjean's watery extract of ergot, diluted with three times as much spirit and glycerine. The injections were repeated every three or four days. Decided improvement is said to have taken place, but pulsation never quite ceased. The improvement commenced after the second injection. No unpleasant symptoms occurred after the injections. In the second case a man, aged 42, had a sacculated aneurism of the radial artery of the size of a hazel-nut. An injection of two grains and a half of the watery extract cured it in one day, as the next day it could not be felt. The injection gave rise to some inflammation of the surrounding cellular tissue, which disappeared in a week.

This accident I have seen happen in one case in which I tried it, but no good resulted from the treatment, which cannot, indeed, on pathological grounds, be considered to be of a hopeful character.

**INTRODUCTION OF FOREIGN BODIES.**—In 1864 Moore introduced twenty-six yards of fine iron wire into the sac of an aortic aneurism through a fine trochar, with the view of inducing coagulation of its contents. The tumour appeared to become more solid, but death took place on the fifth day from inflammation of the sac and pericarditis. Since that time the operation has been repeated about a dozen times without any very encouraging degree of success, the only cure having occurred in a case of a small brachial aneurism in a young woman under the care of Van der Meulin. In this case catgut was used instead of wire, and the treatment was combined with compression. In 1873, Bryant introduced twenty-six feet of horseshair into a popliteal aneurism in a patient dying from ulcerative endocarditis, and thus averted the threatened rupture of the sac, prolonging life for a few days. In 1883 Loreta introduced two metres of wire into the sac of an abdominal aneurism after exposing it by opening the abdomen. The man apparently recovered, but died after ninety-two days from rupture of the sac close to the mouth. Similar treatment was adopted by Morris in a case of abdominal aneurism, but the patient died of asthenia on the fifth day. In 1885, Hulke introduced forty feet of wire into an aortic aneurism, with the result of consolidating a part of the sac which threatened to give way, but eleven weeks after, the tumour was enlarging so rapidly in another direction that the operation was repeated by Gould, but without success. These seem to be the only cases in which any marked benefit has followed the operation. The true value of this treatment has yet to be determined. It is evidently justifiable only when more efficient means are inapplicable, and in such cases it may do something to arrest the progress of the disease. Opinions differ as to the best material to be used. Steel wire, which has been rolled upon a reel so that it may again coil up in the sac, seems the most convenient in many ways, and if too much be not introduced it is not likely to cause any irritation in the sac. Horseshair and catgut are less under control, and may project through the mouth of the sac into the main trunk, although so far there has been no evidence of embolism following their use. The treatment is probably useless after the aneurism has become diffused by the yielding of its sac.

Barwell in one case of aortic aneurism combined electrolysis with the introduction of steel wire. Ten feet of fine steel wire were passed into the sac through a hollow needle made of ivory. The wire was then connected with the positive pole of a battery, the negative being applied to the skin of the back. Some consolidation followed the operation, but the patient died on the ninth day from rupture of the sac. A considerable amount of firm colourless clot was found adhering to the wire, but what part electrolysis took in its production is doubtful.

ACUPUNCTURE with very fine needles has been performed with some benefit in a few cases, and if carefully carried out, can hardly be productive of any injury. It was first suggested by Velpeau, and practised without success by Dunville and Agnew. In this way Marshall obtained some consolidation in more than one case of aortic aneurism. Heath adopted the same treatment in a case of subclavian aneurism in University College Hospital after he had unsuccessfully amputated at the shoulder-joint. Six fine needles were introduced into the sac in such a way as to cross each other, and were left in for four days, at the end of which time the tumour was much firmer. The patient died about twelve days after from causes unconnected with the treatment, and a considerable amount of firm clot was found in the sac. This treatment seems worthy of further trial in otherwise hopeless cases as a substitute for galvano-puncture. The smallest sewing needles with heads made of sealing-wax may be used, as in Heath's case; or better still, the fine pins known as entomological pins, which should be gilded. They may be left in for from four to five days, and should be covered with some simple antiseptic dressing to diminish the risk of ulceration. After they are removed the punctures must be covered with collodion.

Macewen has employed acupuncture in the following way. One or more fine needles, long enough to reach across the sac, are introduced and are left in for twenty-four or thirty-six hours, during which time the position of the point of the pin is frequently shifted, so that it may come in contact with different parts of the inner surface of the sac. The treatment usually needs repetition and no anæsthetic is required: antiseptic precautions must be observed.

Macewen has recorded four cases in which this method was adopted. The first case was an aortic aneurism, which ended fatally by its pressure on the trachea a month after the treatment was commenced; pins had been introduced on seven occasions, and at the *post-mortem* the sac was found to be two-thirds filled with white, firm, laminated thrombus. The second case was a large femoral aneurism which was cured by this method combined with compression of the common iliac artery for two hours, after compression alone a fortnight previously had failed. In the third case an aneurism of the upper part of the abdominal aorta was cured after acupuncture had been used on three occasions. The relations of the stomach and intestines to the surface of the sac were first determined by inflating them with gas. The patient was in good health two and a half years after the treatment. The fourth case was one of intrathoracic aneurism projecting above the clavicle and probably involving the left subclavian; it was accompanied by œdema, pain and loss of power in the left arm. Acupuncture was performed four times in a month, and on five occasions four months later. The improvement was gradual, and twenty-two months after the treatment was commenced the patient was performing her ordinary duties, the use of the arm being

restored. The aneurism could be felt as a hard mass by dipping the fingers behind the clavicle.

#### ARTERIO-VEINOUS ANEURISMS.

Preternatural communication between arteries and veins, though usually the result of wounds, occasionally happens from disease ; ulceration taking place between the vessels, and thus causing an opening from one into the other. When such communications are of traumatic origin, they may, as has already been stated, constitute either an *Aneurismal Varix* or a *Varicose Aneurism*. As the result of disease, aneurismal varix only can occur, varicose aneurism never happening except as a consequence of wound. These spontaneous communications have been met with between the aorta and the vena cava, and between the iliac, femoral, carotid, and subclavian arteries and their accompanying veins. In nature, symptoms, course, and treatment they so closely resemble traumatic aneurismal varix, described at Vol. I., p. 470, that their consideration need not detain us here.

## SPECIAL ANEURISMS.

## CHAPTER XLIV.

## ANEURISMS OF THE THORAX, HEAD AND NECK, AND UPPER EXTREMITY.

## ANEURISM OF THE THORACIC AORTA.

**SYMPTOMS.**—The symptoms of intrathoracic Aortic Aneurism are of two kinds : *auscultatory* and *rational*.

The **Auscultatory Signs** vary greatly in distinctness, and may even be wanting. In some cases, more especially in fusiform aneurisms, they are very marked almost from the first ; in others, especially in sacculated aneurisms, they may be absent throughout. They consist in murmurs of various kinds and degrees of intensity—bellows, rasping, or whizzing ; and in the second sound of the heart being audible over a greater space than normal. At the same time there may be dulness on percussion. These various signs may often be heard upon or to the left side of the spine more distinctly than at the anterior part of the chest ; when occurring anteriorly, they are chiefly met with on the right side.

The value of the auscultatory signs in the diagnosis of aneurism within the chest is not perhaps so great as in many other thoracic diseases in the early stages of the affection, and in those cases in which the aneurism continues small and sacculated throughout, or is so deeply seated as not to approach the parietes of the chest. This is not surprising, when we reflect how deeply the ascending portion of the aorta and the arch are situated ; how they are covered in front by the lungs and loose areolar tissue, through which sound is with difficulty transmitted ; and how they are covered in behind by the spine and its muscles. When, in addition to this, it is borne in mind that aneurisms of the arch often prove fatal by rupture before they have attained a size greater than that of a walnut or a pigeon's egg, and thus are incapable of furnishing a murmur of any very marked kind, it can easily be understood that the value of auscultation is but small in many cases of thoracic aneurism.

The **Rational Signs** of intrathoracic aortic aneurism are of three kinds :—**Pressure-Effects** ; **Pulsation** ; and **Tumour**.

**Pressure-Effects** may be exercised on any of the contiguous structures ; and a glance at the anatomical relations of the thoracic aorta, more particularly the arch, will enable the Surgeon to judge of their complexity and importance. They will necessarily vary according to the size of the aneurism and the

portion of the aorta affected by it; more according to the latter than to the former condition. When the aneurism arises from the *root of the aorta*, and more especially when it is intrapericardial, it is usually of small size, and its pressure-effects will be little obvious. When the aneurism arises from the *termination of the arch*, or the *descending aorta*, it may often attain a considerable development without causing any very obvious pressure-effects. Aneurisms that are situated *within the concavity of the arch* necessarily give rise to very severe effects, by the compression they must exercise upon some one or other of the very important structures that are included within the aortic arch. When the *anterior part of the aorta* is affected, the aneurism may attain a very considerable bulk, even coming forward so as to project and pulsate between the intercostal spaces, without any very noticeable pressure-effects being induced; but when the *posterior wall of the artery* is the seat of the disease, severe symptoms are caused by the compression of the structures lying contiguous to the artery and erosion of the *vertebræ* (Figs. 467, 468). When the *upper part of the aortic arch* is the seat of aneurism, a

Fig. 467.—Erosion of Intervertebral Substance by a small Aneurism of Descending Aorta pressing backwards.

Fig. 468.—Aneurism of Thoracic Aorta, causing erosion of dorsal vertebrae. The intervertebral discs appear unchanged. The aneurism has undergone spontaneous cure, by the deposit of laminated fibrin.

peculiar train of cerebral symptoms, such as vertigo, insensibility, or defective vision, may be induced by its interference with the circulation through the carotids.

The pressure-effects that need chiefly engage our attention are :—1, Pain, 2, Dyspœa; 3, Dysphagia; and 4, Œdema.

1. **Pain** is usually one of the earliest symptoms of intrathoracic aneurism, and is frequently of great value from a diagnostic point of view, as it is often most marked when the other symptoms are least developed. It is generally more severe in sacculated than in fusiform aneurisms, and when the

posterior rather than the anterior aspect of the vessel is the seat of disease. The pain is of two distinct kinds. The first kind is lancinating, intermittent, and neuralgic in its character, evidently dependent upon pressure on adjacent nerves. This pain is seated chiefly on the left side, and shoots up the side of the head and face, down the arm to the elbow, along the intercosto-humeral nerve, through the chest, or between the scapulæ. The second form of pain occurs usually at a later stage of the disease, is continuous, and of a boring, or burning character. It seems to depend upon the perforation of the tissues, more especially the bones, and occurs chiefly on the right side of the chest.

2. **Dyspnoea** is of very frequent occurrence in intrathoracic aneurism; in all probability it is more uniformly met with than any other single symptom. It may arise from five distinct conditions, and its characters vary with its cause.

*a. From direct pressure on the trachea.* In these cases the dyspnoea is attended with much wheezing cough, and often with whistling sounds in the chest and tubular respiration, and with slow expansion of that cavity. There is usually expectoration of thick tenacious mucus. The character of the voice is unchanged.

The tracheal stridor and the voice sound are heard with remarkable distinctness on applying the stethoscope over the upper dorsal vertebrae—the sound being conducted through the bones.

*β. From direct pressure on a bronchus* (Fig. 469). In these cases there are wheezing cough, and some degree of expectoration, with perhaps diminished respiratory murmur on the side affected, and puerile respiration in the opposite lung, as was pointed out by Stokes.

7. *From pressure upon the lung.* In these cases the respiration is comparatively little interfered with, the spongy tissue of the lung accommodating itself and yielding to the pressure of the tumour. After a time the lung tissue will become incorporated with the wall of the sac; and then more serious difficulty in breathing, with hæmoptysis, will supervene.

8. **Dyspnoea** is very commonly induced by *irritation, compression, or stretching of the left pneumogastric and recurrent laryngeal nerves*, by the pressure of the tumour. In these cases the muscles that are supplied by the left recurrent laryngeal nerve may be paralysed, whilst in some cases spasm, accompanied by urgent dyspnoea, occurs from irritation of the nerve before it is pressed upon sufficiently to cause paralysis.

If all the muscles supplied by one recurrent laryngeal nerve are paralysed

Fig. 469.—Aneurism of Arch of Aorta, of the size of an almond, springing from below left Subclavian Artery, and bursting into left Bronchus.

the affected vocal cord is immovable and laryngoscopic examination will show that it assumes the "cadaveric position"—that is, midway between the positions of phonation and full inspiration. The voice is generally weak and hoarse, but there is no dyspnoea.

If both the recurrent laryngeal nerves are paralysed, both the vocal cords assume the position above described. Those acts, such as phonation and coughing, which require approximation of the cords, are therefore impossible. Dyspnoea may still be altogether absent.

In many cases of pressure upon the recurrent laryngeal nerve all the muscles supplied by it do not suffer equally. Under these circumstances it is the *crico-arytenoideus posticus* muscle that is chiefly affected, and as this is the principal abductor of the vocal cord the latter is drawn inwards by the unopposed adductors into a position of phonation. In adults this unilateral abductor paralysis is often unattended with any alteration in the voice or with difficulty of breathing, and thus as Semon, writing in Heath's Dictionary of Practical Surgery, remarks, "the important laryngeal lesion present, which may be of the greatest importance for the correct diagnosis of the whole case, will entirely escape notice, unless a rule be made to examine the larynx in all cases in which lesions of the laryngeal nerves could occur, whether there be symptoms pointing to the larynx or not." If the partial paralysis be bilateral—the abductor on each side being chiefly or solely affected—both cords are drawn inwards so as nearly to meet in the middle. Under these circumstances the voice may still be unchanged, but there will be inspiratory stridor and a varying degree of dyspnoea.

As a rule the paralysis of the larynx, resulting from the pressure of an aortic aneurism upon the left pneumogastric, is unilateral. This is invariably so in the case of the recurrent laryngeal branch, but George Johnson and others have shown that pressure upon one pneumogastric trunk may occasionally lead to paralysis of both sides of the larynx, either partial or complete.

The laryngeal symptoms are sometimes so much more prominent than any of the other signs of intrathoracic aneurism, and so closely resemble chronic or even acute laryngitis, with impending asphyxia, that there are not a few cases on record in which Surgeons have performed tracheotomy, on the supposition that they had to do with cases of pure and uncomplicated laryngeal disease; and in other instances this operation has been performed with a view of prolonging life, even when the dependence of the laryngeal spasm on aneurism of the aorta has been recognized.

c. Dyspnoea may be dependent on *compression of the pulmonary vein* by the aneurismal tumour. In cases of this kind there would be considerable lividity of surface, and signs of pulmonary congestion.

The dyspnoea of intrathoracic aneurism will often be sufficiently intense to occasion death. It may be mistaken for ordinary asthma; but the diagnosis can usually be made, by observing that in aneurism the paroxysms of dyspnoea often come on in the day as well as at night, and are greatly increased by change of position, as by placing the patient either upright or recumbent, the tumour thus shifting its point of pressure. It is, as Bellingham has pointed out, not influenced by atmospheric changes, and is generally associated with laryngeal stridor or spasm. When such symptoms as these are associated with pain and dysphagia, they point very strongly, even in absence of all auscultatory signs, to the presence of an aneurismal tumour.

Aneurisms situated within the concavity or springing from the posterior parts of the aortic arch are those which, either directly by their pressure on the air-tubes or the pulmonary veins, or indirectly by the influence they exercise on the recurrent laryngeal nerve, are chiefly associated with dyspnoea.

3. **Dysphagia** is a symptom of sufficiently frequent occurrence in aneurisms of the thoracic aorta. It seldom occurs, however, in the earlier stages of the disease, or when the aneurism is small, and hence is of much less diagnostic value than dyspnoea. When, however, it is associated with that symptom, the combination becomes important; as the co-existence of the two conditions clearly points to the compression of the œsophagus and the air-tubes by a tumour, which other diagnostic signs may prove to be an aneurism.

It is of importance to bear in mind that in some aneurisms, especially of the descending thoracic aorta, dysphagia may be one of the most marked signs. In such cases as these, stricture of the œsophagus has erroneously been supposed to exist, and the patient has even been treated by the introduction of bougies—an error of practice that has terminated fatally from perforation of the aneurismal sac, where it projected against the œsophagus.

The difficulty in deglutition in cases of compression of the œsophagus by aortic aneurism, is almost invariably referred to the episternal notch. The dysphagia is commonly associated with pain, or with the sensation of a cord drawn tightly around the body.

4. **Œdema**, with more or less lividity of the upper extremities and head and neck, occasionally though rarely occurs. It is generally most marked on the left side, and arises from the compression of the superior cava or the innominate veins by aneurisms springing from the fore or upper part of the arch.

**Pulsation and Tumour**, observable externally, are always absent in the early stages of intrathoracic aortic aneurism, and very frequently continue so to the end; indeed, in aneurisms springing from the intrapericardial aorta or the concavity of the arch, death usually takes place, either by rupture into one of the serous cavities or the air-tube, or, by the exhaustion induced by dyspnoea, long before the aneurism has attained a sufficient size to be recognizable externally. There are, however, three portions of the thoracic aorta which, when affected by aneurism, yield external evidence by the existence of pulsation or tumour of the true nature of the disease. These are—1, the anterior aspect of the ascending aorta; 2, the summit of the arch; and 3, the posterior aspect of the descending aorta.

1. When the aneurism is situated *on the anterior aspect of the ascending aorta and commencement of the arch*, pulsation may be detected by pressure between the intercostal spaces on the right side of the sternum, and a thrill, as well as distinct impulse, may often be felt over that side of the chest, before any external tumour becomes visible; thus simulating the beat of the heart, in addition and opposite to the seat of the true cardiac impulse. As the aneurism increases an external tumour appears, the wall of the chest becoming absorbed and perforated opposite the point of greatest impulse.

2. When an aneurism springs from *the summit of the arch*, a pulsating tumour appears at the root of the neck, behind or even above the margin of the sternum, most commonly towards the right side, and occasionally rises so high out of the thorax, and is so distinctly felt in the neck, as to run the risk of being confounded with aneurism of the innominate or carotid artery

(Fig. 474, p. 170). This error, which has frequently been committed, and which has led to operations on the arteries at the root of the neck, may usually be avoided, except in the case of the innominate, by the impossibility of tracing with the finger the lower boundary of the tumour, and the existence of distinct dulness on percussion, and possibly of impulse or of auscultatory evidence of aneurism, below the level of the upper margin of the sternum or clavicle.

3. When an aneurism springs from the *posterior wall of the descending aorta*, a pulsating tumour may gradually develop to one side of the spine or under the scapula, commonly on the left side; and it may attain a great size, fully as large as a man's head, before the patient is destroyed by the rupture of the tumour externally.

**TREATMENT.**—In the great majority of aneurisms of the thoracic aorta surgical interference is impossible, and our sole reliance must be placed on rest, diet, and the administration of iodide of potassium (see p. 118).

**Surgical Treatment of Aneurism of the Aortic Arch.**—The idea of treating aneurism of the aortic arch by ligature of one or two of the main arteries at the root of the neck, originated in the results of an operation performed by Christopher Heath in 1865 for the cure of a supposed innominate aneurism by the simultaneous ligature of the right carotid and subclavian arteries. The patient, a woman of intemperate habits, survived the operation for four years, appearing for a time to have been benefited by it. On her death it was found that the aneurism was not one of the innominate but of the ascending aorta, and that it had been practically cured by or after the operation. About the same time Cockle was engaged in a series of observations on the spontaneous consolidation of aneurisms of the aortic arch; he found that in some of these cases the *left* carotid artery had become occluded, and he inferred from this that ligature of that vessel might be of use in the treatment of certain forms of aneurism of the arch. This suggestion was acted on by Heath, who, in 1872, tied the left carotid artery in a patient of Cockle's affected with aneurism of the ascending and transverse portions of the arch. The patient was benefited by the operation. Heath's second case proved fatal from syncope: in his third case the aneurism appeared to diminish in size for a while, but then rapidly increased, and the patient died suddenly two months after the operation. Barwell has operated in two cases, in one with advantage. In the other, in which the left subclavian was also tied, the patient died, apparently uninfluenced for good or ill by the operation. In all, the operation appears to have been done 13 times (Ashurst)—in six cases with more or less benefit. In at least four of these cases the artery was ligatured on the supposition that the aneurism was situated at the root of the carotid, when, in reality, it occupied the arch. Barwell states that, in those aneurisms which spring from the aorta beyond the left carotid, ligature of this vessel will do more harm than good, and that the operation should be confined to those in which the tumour appears on the left side, but not far from the median line, and rises into the episternal notch or under the left sterno-mastoid.

The **Simultaneous Ligature of the Right Carotid and Right Subclavian Arteries** for aneurism of the aortic arch has, according to Barwell, been done only in three cases for aneurism diagnosed as aortic before the operation. In some other cases, as the one referred to above, diagnosed

erroneously as innominate, but proving in reality to be aortic aneurism, it has also been done. In the three cases of recognised aortic aneurism the operations were done by Barwell, Lediard, and Wyeth. In all, the ox-aorta ligature was used, and the patients lived 15 months, 8½ months, and one year respectively after the operation (Barwell). Wyeth tied the left subclavian and left carotid in a case of aortic aneurism, but the patient died 72 hours after the operation.

The ligature of one or more of the main arteries at the root of the neck for the cure of aneurism of the aortic arch involves a new principle in the treatment of that disease : one that differs in all respects from that in which the cure of an ordinary external aneurism is effected, viz., the arrest or retardation of the circulation through the sac so as to facilitate the deposit of laminated fibrin or firm clot. In the treatment of aortic aneurisms by ligature of the left carotid only, or by that of the right carotid at its root, and of the right subclavian in the third part of its course, the operation does not in any way diminish or retard the flow of blood through the aorta or lessen the quantity sent into the aneurismal sac. Moreover, the ligature of the artery by interposing abnormal resistance in the circulation would cause increased tension in the sac as well as in the arteries generally, until the dilatation of the anastomosing vessels had relieved the obstruction. Thus the very reverse of what happens in the Hunterian or ordinary distal operation takes place when one or more of the primary branches of the aortic arch are tied. It has been suggested that coagulation in the aneurism may be the result of the direct extension of the thrombus into it from the point of ligature. Heath does not accept this explanation, but suggests that an altered condition of circulation through the sac may lead to the deposit of laminated fibrin.

That some benefit appears to have followed these operations in a few of the cases is undoubted ; but how much of this may fairly be attributed to the direct influence of the operation appears to me to be very uncertain. For it cannot be doubted that the confinement to bed after the operation, and the more careful and regulated life that would be led by those who had been subjected to so serious a procedure, must exercise a very beneficial influence upon any external aneurism ; and it may fairly be a question whether a patient, subjected to an operation that would require absolute rest for several weeks and subsequently necessitate a quiet and carefully regulated life, would not derive as much benefit as the patients in whose necks large arteries have been tied for the cure of aortic or even of most innominate aneurisms have done.

The necessity for hesitation in the adoption of these operations for the cure of aortic aneurism appears to me to be strengthened by the difficulty, in many cases, of making a correct diagnosis of the exact seat of the aneurism, whether it be innominate or aortic, or both, or, if aortic, from what part of the arch it springs ; and also in determining with absolute certainty whether a given intrathoracic tumour be an aneurism or not.

The immediate danger of these operations, whether done for aortic or innominate aneurism, is also very considerable. A very large proportion of the patients so operated on died within a fortnight, and in some cases death resulted immediately or within a few hours from the disturbance of the circulation through the brain by the ligature of one of the greater arteries springing from the arch.

Another fact of much importance that cannot be ignored in considering the advisability of subjecting a patient with supposed aortic aneurism to the operation of ligature of the carotid and subclavian arteries is the undoubtedly very slow progress and prolonged duration of many of these aneurisms, and the possibility of a spontaneous cure in some. Patients with aortic aneurisms frequently live for several years after the disease has been recognized. Under proper constitutional treatment the severity of the symptoms may be greatly mitigated, and in all probability the chances of cure would be about equal under the two modes of treatment—the strictly surgical and the medical—whilst speedy or sudden death would be more likely to occur to those subjected to the operation.

Attempts to obtain consolidation of the tumour by the introduction of coils of iron wire, catgut, or horsehair, have not as yet been attended with any marked benefit to the patient (see p. 150).

The mode of treatment which has been more frequently adopted than any other is **galvano-puncture**; and it seems probable that in well-selected cases this may be productive of good, or may even occasionally lead to a cure. In 27 cases of aortic aneurism thus treated, which have been collected by John Duncan, 5 were cured, 10 relieved, 9 unrelieved, and 3 died. Experience has shown that with well insulated needles and a suitable battery there is scarcely any danger to life, and that the operation, even when it does no good, does no harm. It has been applied in all stages of the disease, from the time when the tumour becomes sufficiently superficial to allow the safe introduction of the needles, to the time when it has perforated the chest-wall, and is on the point of bursting. In one of Duncan's cases, the life of the patient was undoubtedly prolonged for nearly three months after the time at which, if left to itself, the aneurism would have burst externally. The cases best suited for galvano-puncture, and in which even a cure may occasionally be hoped for, are those in which the tumour is of slow growth, has not yet perforated the chest-wall, and in which it can be diagnosed as sacculated and communicating with the aorta by a comparatively small opening. It is important also that the patient's health should not be too much broken by suffering or visceral disease. When the tumour projects through the parietes of the thorax, forming a secondary sac outside, the prospect of cure is infinitesimally small; but even then, progress may be delayed, and much relief given to the patient. If the tumour have become diffused, as may occur when it points in the back, galvano-puncture can only do harm by increasing the tendency to inflammation and suppuration already existing. For the details of the operation, see page 147.

There is one point in the treatment of some forms of aortic aneurism, that falls more within the province of the Surgeon, and on which his opinion may be sought. I mean the advisability of **opening the windpipe**, to relieve the patient from the distress occasioned by the laryngeal spasm or paralysis that commonly attends many of these cases. The decision of this question is always an anxious one; for it must be borne in mind that, as the disease which occasions the spasm of the larynx is inevitably fatal, the operation can be expected to give only temporary relief.

In determining this question, the Surgeon must bear in mind that simple laryngeal spasm is rarely, if ever, the direct cause of death in aortic aneurism; that, although the patient may suffer greatly from this complication, he does

not die of it ; but that the ultimate cause of death is usually intrathoracic pressure, rupture of the sac internally or externally, or exhaustion. The operation, therefore, would be justifiable in those cases only in which it could be determined that the spasmodic dyspnoea was purely laryngeal, and was not dependent on compression of the air-passages within the chest by the aneurismal tumour, but simply on the irritation produced by the implication of the left recurrent laryngeal nerve. Such cases are very rare, and necessarily most difficult of accurate diagnosis. As the Surgeon will usually get the credit of having killed the patient if he be induced to perform the operation, and the relief be not immediate and great, I would advise him not to operate unless the diagnosis be most clear, or in circumstances of imminent death from laryngeal spasm, with the view of affording immediate, even if it be only temporary, relief. If any operation be done, it should certainly be laryngotomy, and not tracheotomy.

#### ANEURISM OF THE INNOMINATE ARTERY.

Aneurisms of this artery are very frequently accompanied by dilatation or actual aneurism of the aorta. Innominate aneurisms may be either of the tubular or the sacculated kind, and usually give rise to a train of serious and dangerous symptoms, from their pressure upon important parts in their neighbourhood. Indeed, a glance at the relations of this artery will show the important effects that must be produced by the pressure of a tumour springing from it. Crossing it is the left innominate vein ; to the outer side are the lower cervical cardiac branch of the pneumogastric, the right innominate vein, the right pneumogastric and the pleura ; behind it and to its inner side is the trachea. An innominate aneurism may extend backwards so as to come into relation with the œsophagus, and upwards so as to press on the right recurrent laryngeal nerve.

**SYMPTOMS.**—The general symptoms of an aneurism of the innominate artery are the existence of a pulsating tumour of a globular shape behind the right sterno-clavicular articulation, attended with pain, and perhaps œdema of the right side of the face and right arm, with some difficulty in respiration, laryngeal cough, and dysphagia. The tumour is usually soft and compressible, filling up more or less completely the hollow above the sternum, and even rising as high in the neck as the lower margin of the cricoid cartilage ; it pushes forwards, first the sternal, and afterwards the clavicular portion of the sterno-mastoid muscle, and has occasionally been seen to extend into the posterior inferior triangle of the neck ; and, indeed, is generally most distinctly defined towards its brachial aspect. In some cases no tumour rises into the neck, but the sternum, clavicle, and costal cartilage of the first rib, are found to be considerably pushed forwards. In the space around the right sterno-clavicular articulation, and about the upper part of the sternum, there will be dulness on percussion, and marked pulsation is often felt in the first intercostal space. In very many instances there is no bruit, but merely a strong impulse with the heart's sounds, as distinct as in the cardiac region, or even more so ; but in other cases there may be every variety of bruit.

**Pressure-Effects.**—The most important symptoms are occasioned perhaps

by the pressure-effects of the tumour upon the neighbouring parts, affecting the pulse, the venous circulation, the nerves, respiration, and deglutition.

The **Pulse** is usually influenced, being much smaller and feebler in the radial artery of the affected than in that of the sound side, and in some instances being completely arrested; owing, doubtless, to pressure on or occlusion of the subclavian. The pulsation in the right carotid and its branches is also frequently much less powerful than in the opposite vessel. These signs commonly occur before any external tumour is seen or can be felt, and hence constitute an important element in the early diagnosis of the disease.

**Enlargement of the Superficial Veins** of the neck and right upper extremity is of frequent occurrence, the external jugular being the vessel that is usually first evidently dilated; at a more advanced period the superficial subcutaneous veins of the upper part of the right side of the chest often become tortuous and form a dense plexus in this situation, while many anastomose with the cephalic and thoracic veins above, and the superficial epigastric below. As the pressure increases, œdema commences in the right eyelids and hand, and may speedily extend to the whole of the head, face, and arm, which become hard and brawny in consequence of serous infiltration. In one instance I have seen the left arm suddenly become œdematous, the left innominate vein being pressed upon. In these cases the eyes become staring and prominent, and the lips, nose, and other features livid and turgid with blood, as well as œdematous, so as greatly to alter the expression of the countenance.

**Pain** of a dull aching character is felt in the situation of the tumour, from the compression of the neighbouring structures. But in the later stages of the disease the patient often experiences sharp shooting pains resembling those of rheumatism or neuralgia, in the arm and the side of the head and face, arising from pressure upon, and irritation of, nerves of the cervical and brachial plexuses. Taking the course of the ascending and descending filaments of the cervical plexus, the pain shoots up the side of the head and neck, and over the shoulder and upper part of the chest; or, from pressure upon the brachial plexus, it radiates down the hand and arm, being usually especially severe about the elbow and fingers. The muscular power of the right arm also commonly becomes impaired. Persistent dilatation of the vessels, with sweating of one side of the face, occasionally occurs from pressure on the sympathetic.

**Dyspnoea** is of very common occurrence, and of very varying degrees of intensity, from slight difficulty in breathing up to fatal asphyxia. It may proceed either from compression of the recurrent nerve, or from pressure on the trachea. When it depends on the former condition, the voice is hoarse, husky, or whispering; and there is a dry, croupy, and paroxysmal cough, usually accompanied by expectoration of thin frothy mucus. In these cases, after death, the right recurrent nerve will be found to be stretched out and greatly elongated by the pressure of the tumour (Fig. 470). Compression of the trachea, which becomes flattened and curved over to the left side by the protrusion of the tumour, is a common cause of dyspnoea, and is not unfrequently associated with pressure on the recurrent nerve. More rarely by far, the right bronchus is compressed by the extension of the tumour downwards.

**Dysphagia** is of sufficiently frequent occurrence, and varies from slight uneasiness in deglutition to an impossibility of swallowing anything except

fluids. I have never seen it occur without having been preceded by dyspnoea ; and, in every instance that has fallen under my observation, it has been associated with laryngeal dyspnoea. The coincidence of these two symptoms is readily explained by the anatomy of the parts ; the recurrent nerve, lying between the sac and œsophagus, must suffer compression before the mucous canal can be interfered with.

**PROGNOSIS.**—The prognosis of innominate aneurism is in the highest degree unfavourable, though the disease frequently does not run a rapid course. If it extend upwards and outwards, the tumour may attain a very large size before any very important organ or part is implicated ; but if it press backwards and inwards, it may prove fatal at an early period. I know of only one case of spontaneous cure (reported by J. Ogle), and but few instances in which rupture of the sac has taken place. The most frequent cause of death is asphyxia, from spasmodic closure or paralysis of the larynx induced by pressure on the recurrent nerve ; or from pressure on the trachea.

**DIAGNOSIS.**—The diagnosis of innominate aneurism is usually sufficiently easy, if attention be paid to the symptoms that have just been detailed. But at times the difficulty is so great as to baffle the most sagacious Physicians and most experienced Surgeons ; that which has during life been considered to be an aneurism of the innominate artery, having, after death, proved to be one of the summit of the aortic arch rising up into the root of the neck behind the right sterno-mastoid, or overlapping the innominate trunk. The task of overcoming this difficulty in diagnosis must be left to the skill of the Surgeon. But it is impossible to over-

estimate its importance, when the question of ligaturing the arteries at the root of the neck for a supposed innominate aneurism is considered ; for, in at least three cases in which this operation has been done, the arch of the aorta has been found to be the seat of disease, the innominate in two of the cases being unaffected by aneurism. I am acquainted also with a fourth case, in which the operation was commenced, but was abandoned, as the subclavian could not be reached ; the patient dying a few days afterwards, the aneurism was found to be aortic, rising up into the root of the neck, the innominate being sound.

**TREATMENT.**—There are several instances on record in which a properly conducted course of constitutional treatment has cured the patient : thus a case of Luke's was permanently cured by small and repeated bleedings, conjoined with the administration of digitalis. In connexion with such treatment, distal pressure may be employed, as in a case that derived benefit from this plan in Syme's hands.

In aneurism of the innominate, the vessel is so short, and the sac so situated, that it is impossible to attempt to apply a ligature on the cardiac side of the

Fig. 470.—Aneurism of the Innominate Artery compressing and stretching the Recurrent Laryngeal Nerve, and pushing the Trachea to the Left Side. (Back View.)

tumour. What resource, then, does surgery offer in these cases beyond the employment of constitutional and dietetic means? If these measures fail in arresting the disease, our choice must lie between leaving the patient to his fate, or having recourse to the application of the ligature on the distal side of the tumour. On looking at the innominate artery with reference to the distal operation, we are struck by two peculiarities in the vessel, which must necessarily modify to a considerable extent not only the seat of the operation, but the principle on which it is conducted. The first peculiarity is the shortness of the trunk, which makes it impossible to apply the ligature to the vessel itself, but renders it necessary to tie one or both of its terminal branches. The other peculiarity is, that in no circumstances can these vessels be so ligatured as to arrest the whole of the blood sent into the artery; for, although the circulation through the carotid may be entirely stopped, yet it is impossible, from the seat and extent of the disease, to tie the subclavian at any point except beyond the *scaleni*; hence that blood which is destined for the supply of the branches of this vessel—the vertebral, the thyroid axis, the internal mammary, and the superior intercostal—must continue to pass through the sac. Three distinct modifications of the distal operation have been proposed and resorted to for the cure of aneurisms in this situation: 1. Ligature of the Subclavian alone: 2. Ligature of the Carotid alone: and 3. Ligature of both vessels with an interval of greater or less extent.

1. **Ligature of the Subclavian only** (Fig. 471) has been practised by Dupuytren, Wardrop, Laugier, Broca, and others. Dupuytren's and Laugier's cases were soon fatal, and Broca's experienced no relief and died in six months. In Wardrop's case the tumour diminished and the patient survived for two years. This partial success may fairly be attributed in a great measure to the accident of the carotid having been occluded by the disease. The results of this practice have certainly not been sufficiently favourable to justify the Surgeon in repeating an attempt of this kind, opposed as it is to the known principles on which the distal operation effects a cure. For, supposing as we may safely do, with Wardrop, that only one-third of the blood that is sent into the innominate finds its way through the third part of the subclavian, the remainder being destined for its branches and the carotid in equal proportions, what fact can be adduced or principle laid down from which we can expect to obtain the cure of an aneurism in close proximity to the heart, by cutting off for a short time only so small a proportion as one-third of the supply of blood sent into it? As soon as the collateral vessels have dilated, the flow of blood through the artery will be the same as before the operation, as the supply of blood to the upper limb is maintained by means of the anastomoses of the branches of the first and second part of the subclavian with those of the axillary artery.

2. **Ligature of the Carotid only** (Fig. 472, p. 165) for innominate aneurism was first performed by Evans in 1828. The tumour diminished for a few days after the operation, but at the end of seven days inflammation of the sac set in, followed by obliteration of the arteries of the right arm and the branches of the carotid. At the end of a year a tumour still existed, with constant pulsation. Next year the sac suppurated, and discharged much pus. Since that time the operation has been repeated by Mott, Aston Key, Ferguson, Hutchinson, Pirogoff, and many others, amounting in all to about thirty cases. In only one case, that operated on by Evans, does the disease appear

to have been materially relieved; and in that instance the good effects can hardly be attributed to the operation, but must rather be looked upon as the result of suppuration of the sac and consequent obliteration of the arteries of the arm and head of the affected side. Key's patient died in consequence of the left carotid becoming occluded and the brain being deprived of its proper supply of blood; and in several other cases death is referred to hemiplegia and other cerebral diseases.

3. The **Carotid and Subclavian Arteries** (Fig. 473) were tied simultaneously for the relief of innominate aneurism for the first time by Rossi in 1848, but there is some doubt as to the part of the artery to which the ligature was applied. Since that time Winslow of Baltimore has collected thirty-three cases in which this operation has been performed; this includes the cases collected by Holmes, Wyeth, Rosenstern, and Barwell. Of these 34 cases

Fig. 473.—Innominate Aneurism: Ligature of the Subclavian and Carotid.

22 recovered from the operation. Four of these died after periods varying from two to six months from causes directly connected with the aneurism—two from rupture of the sac, one from hæmorrhage from the trachea, and one from dyspnœa. In five cases the effect of the operation is not stated. One case is merely stated to have been improved and another not cured. Of the remaining 11 cases which recovered, 2 were still alive and well when last seen: 5 seemed to be cured or were improved after periods varying from six months to 3 years. Little's case lived three and a half years, dying at last of pleurisy; the aneurism was practically cured. One of Barwell's cases died after twenty months of bronchitis, another after 3 months from the same cause, and Stimson's cases after twenty-one months of phthisis; in all of these the aneurism was practically cured. Of the 12 fatal cases four died from hæmorrhage, two from rupture of the sac, two from asphyxia, one from cerebral anæmia, one from exhaustion, one from shock, and one from the anæsthetic.

The carotid and subclavian have also been tied consecutively at intervals varying from two years to one month, in six cases, by Fearn, Wickham, Maligne, Mott, Bickersteth, and Adams and Treves. In all cases the carotid was tied first. In Fearn's case two years elapsed between the operations, and the patient died four months after the subclavian was tied, of pleurisy. The aneurism was found to be consolidated, with the exception of a channel leading to the subclavian. In Wickham's case relief followed the ligature of the carotid, but symptoms soon returned, and the subclavian was tied about six weeks afterwards, but without effect, the patient dying in two and a-half months from rupture of the sac. In Mott's case a practical cure resulted, the patient dying of phthisis three years after the second operation. In Adams and Treves's case the aneurism was consolidated, but death took place 108 days after the second operation from rupture of the sac of an aortic aneurism. In the remaining cases no benefit was derived from the operation.

A summary of the cases of aneurism of the innominate, in which the operation of ligaturing one or both arteries beyond the sac has been performed, having thus been given, the question arises whether these operations, or any of them, should retain a place in surgery. This question may be examined from two points of view : 1. As to the principle on which these operations are performed; and 2. As to their results in practice. For the success of the distal operation it is requisite that there be no branch given off, either from the sac or between it and the ligature; or that the current of blood through the sac be at least so far diminished as to admit of the deposit of laminated fibrin in sufficient quantity to fill it up, by a process similar to that which takes place in a case of aneurism treated by the Hunterian method. In order that this may be accomplished, it is certainly necessary that the greater portion of the blood passing through the sac be arrested; for if the current that is still kept up be too free, the tumour will continue to increase, as I have seen happen in cases of inguinal aneurism in which the femoral artery was ligatured below the epigastric and the circumflex ilii, the current through which was sufficient to feed the sac in such a way that a cure could not be accomplished. If, therefore, but one of the vessels leading from the innominate, as the subclavian beyond the *scalen*i, be tied, and but a third of the blood circulating through the main artery be arrested, are we justified in hoping that the circulation through the sac will be so influenced that the remaining two-thirds of the blood, which will still pass through for the supply of the carotid and the branches of the subclavian, will gradually deposit those fibrinous laminae by which the cure is to be effected? Surely, if the comparatively small streams of blood that pass through the epigastric and circumflex ilii are sufficient to interfere with the cure of an inguinal aneurism after the distal ligature of the femoral, the strong current that sweeps through the carotid and the large branches springing from the subclavian, with the full force derived from close proximity to the heart, will most probably be sufficient to prevent all lamination in an aneurism of the innominate. That the arrest of the circulation through one of these vessels only is not sufficient materially to influence the growth of the aneurism, is evident likewise from what is not unfrequently observed after death in cases of this kind. One or other of the vessels may be found compressed and obliterated by the pressure of the sac, or plugged by fibrin, and yet no alteration in the tumour has resulted; and if we turn to the results of

the cases in which either the carotid or the subclavian has been ligatured, we shall find that in one case only, that operated on by Evans of Belper, has a cure been effected. In this case, however, the cure was probably chiefly due, as Guthrie pointed out, to the accidental occurrence of inflammation, which extended to the sac, and thus obliterated it.

In the case (that of Mrs. Denmark) in which Wardrop tied the subclavian for the cure of aneurism of the innominate, there is some reason to doubt whether the arrest of the progress of the tumour was owing to the ligature of the subclavian artery, or whether it was not much influenced by the obstruction which existed in the carotid for nine days after the operation, during which time so abundant a deposit of laminated fibrin might have occurred as to arrest the progress of the disease for some length of time. In this case also, Guthrie thought it probable that the inflammation of the tumour might have led to its obliteration.

From a careful consideration of all the circumstances of the cases in which ligature of one vessel only, either subclavian or carotid, has been employed for innominate aneurism, we are, I think, fully justified in concluding that in the majority the fatal result was accelerated by the operations. In two of the few cases in which improvement occurred, this was the result of accidental circumstances, which were unexpected, and unconnected in any way with the principles on which the operation was undertaken. These results would not, in my opinion, justify any Surgeon in again making an attempt to cure an innominate aneurism by the ligature of either the subclavian or the carotid artery alone.

We have yet to consider the operation in which both arteries are ligatured. This double operation may either be performed *with an interval between the application of the two ligatures*, sufficient for the establishment of collateral circulation ; or the two vessels may be ligatured simultaneously. The results of these operations have already been considered, and of those in which the two vessels have been ligatured simultaneously it is interesting to note that the later cases have been the most successful, and it is reasonable to hope that this is due to modern improvements in the methods of tying arteries and dressing wounds. The cases, however, are not yet sufficiently numerous or free from modifying circumstances to make it possible to draw any certain inference from them ; we must therefore revert to the principle on which this operation should be undertaken. This will differ materially, according as the two arteries are ligatured simultaneously, or with a sufficient interval for the re-establishment of collateral circulation.

If an interval of two years, as in the first case, or even of two-and-a-half months, as in the second instance, be allowed to elapse between the ligature of the carotid and that of the subclavian, the operation reduces itself essentially to that of the ligature of a single artery, which, as has already been shown, is insufficient to induce those changes in the sac that are necessary for the accomplishment of a cure. If the patient survive the effect of the ligature of the carotid for a few weeks, sufficient time will have been afforded for the proximal end of the subclavian, the vertebral artery, and the thyroid axis to undergo great development—the collateral circulation being carried on by them and not by the left carotid ; so that, by the time the subclavian comes to be ligatured beyond the scaleni, the sac will still continue to be traversed by a current of blood for the supply of the branches of the

subclavian, dilated beyond their normal size in consequence of the task of supplying the right side of the neck, face, head, and brain being principally thrown upon them. This current through the proximal end of the subclavian, increased as it will have been by the whole of that blood which is destined to supply the place of that which should pass by the carotid, will place the sac in nearly the same condition as it was before the ligature; and will consequently, for the reason that has already been given, be too powerful for a cure to take place in the course of its stream.

It now only remains for us to consider the *simultaneous* ligature of both vessels. In reasoning upon the simultaneous ligature of the two vessels, we must consider two points: 1. In what condition do we place the sac? 2. Is the danger of the patient much increased?

So far as the *sac* is concerned, it is impossible to place it in a better condition for the deposit of laminated fibrin: two-thirds of the blood flowing through it being arrested, and only that traversing it which is destined for the supply of the branches of the subclavian. It is by no means improbable that even this stream may be too large and forcible to allow the process of occlusion to take place, yet it is impossible further to diminish it; and if the aneurism be sacculated, and project from one side of the innominate artery, particularly to its internal or mesial aspect, it is by no means impossible that it may be sufficiently removed from the stream to allow consolidation of its contents.

Does it add to the danger of the patient to ligature these two vessels simultaneously rather than separately? I think not. If the risk of a double operation is to be incurred, I cannot think that it would be positively increased by the two being performed at once, instead of with an interval between them; the whole of the vessels that serve to maintain the collateral circulation in the head and upper extremity being left without interference. And the result that has followed the limited number of these operations confirms this opinion, for we find that the patients recovered from the operations in twenty-two out of thirty-four cases.

The result of these twenty-two cases, so far as the aneurism itself was concerned, was not altogether unsatisfactory when the otherwise hopeless nature of the disease is taken into consideration. In twelve the patient derived great and unmistakeable benefit, and in the remaining ten there is no reason to believe that the operation hastened death. So far, then, as actual results go, it is evident that the chances are decidedly against the patient's deriving any benefit from the operation, and at the same time it must not be forgotten that aneurisms of the innominate artery have been cured by palliative and constitutional treatment. It does not seem justifiable, therefore, to resort to the distal ligature till these means have had a fair trial. If, however, rest, diet, and medical treatment fail to arrest the progress of the disease, the amount of success obtained from simultaneous ligature of the carotid and subclavian has been quite sufficient to encourage a repetition of it in well-selected cases.

#### ANEURISM OF THE CAROTID ARTERY.

**Aneurismal Varix of the Carotid Artery and of the Jugular Vein,** as the result of punctures and stabs in the neck, has been met with in a sufficient number of instances to establish the signs and treatment of such a condition; and an instance is related by Mackmurdo, in which a com-

munication was established between these vessels as the result of disease ; but I am not acquainted with any case of *Varicose Aneurism* of these vessels having been recorded. The *Signs* of aneurismal varix in this situation present nothing peculiar ; and the *Treatment* must be entirely of a hygienic character, no operative interference being likely to be attended with any but a fatal result. It is the more desirable not to interfere in these cases, as the disease does not appear to shorten life.

**Spontaneous Aneurism of the Carotid** is not of very unfrequent occurrence : in Crisp's table of 551 aneurisms, 25 were of the carotid ; and it ranks in order of frequency between those of the abdominal aorta and of the sub-clavian. It occurs more frequently in the female than any other external aneurism : thus, of the 25 cases alluded to, 12 were in women. This is owing probably to its seldom being the result of violence, but generally arising from disease of the coats of the vessel. In Holmes's table of 337 aneurisms, 11 were of the common carotid, 10 being spontaneous, and 1 traumatic. Three of the former were in women. This aneurism is also remarkable as occurring at earlier ages than most others : thus, Hodgson has seen it in a girl of ten ; Sykes, of Philadelphia, in one of eighteen ; Heath in a woman aged twenty-three (external carotid), who was suffering from extensive disease of the cardiac valves. The right carotid is much more commonly affected than the left, and the upper portion of the vessel than the lower ; the bifurcation being the most common seat of the disease. The root of the right carotid not uncommonly is dilated ; but I have never heard of a case in which the left carotid has been affected in the chest.

**SYMPTOMS.**—A carotid aneurism in the early stage forms a small, ovoid, smooth tumour, with distinct pulsation and bruit, and a well-circumscribed outline. It is commonly soft and compressible, diminishing in size on pressure, and expanding again with the usual aneurismal dilatation. As it increases in size, it becomes more solid, occasions shooting pains in the head and neck, and, by its pressure on the pharynx, œsophagus, and larynx, causes difficulty in deglutition and respiration ; sometimes the salivary glands are much irritated. After a time, the cerebral circulation is interfered with, giving rise to giddiness, impaired vision of the corresponding eye, noises in ear, and a tendency to stupor. These symptoms may be owing to compression of the jugular, to difficulty in the transmission of the blood through the tumour, or to irritation of the cervical ganglia of the sympathetic. The size which these aneurisms may attain varies greatly : usually they are confined to the space under the angle of the jaw, but not unfrequently they occupy the greater part of the side of the neck. If they be allowed to increase without interference, death may happen, either by rupture externally, or into the pharynx or œsophagus ; by asphyxia, from pressure on the larynx or recurrent nerve ; or by starvation, from compression of the œsophagus.

Aneurisms of the carotid are usually of slow growth, and may sometimes exist for years without giving rise to any special inconvenience ; this is more particularly the case when they are seated at the bifurcation of the artery. I have, however, seen an aneurism in this situation attain the size of a small orange in a few weeks. When at the root of the neck, they are more likely to be attended with injurious pressure-effects at an early period.

**DIAGNOSIS.**—The diagnosis of carotid aneurism is more difficult than that of any other external aneurism, and the best proof of this is, that the carotid

artery has been ligatured for supposed aneurism in several instances when no such disease existed—cysts, or other tumours of the neck having been mistaken for aneurism, and this by Surgeons of acknowledged skill.

The diagnosis of aneurism of the lower part of the carotid from *similar disease of other arteries* at the root of the neck, as of the subclavian, vertebral, and innominate, and the arch of the aorta, is surrounded with difficulties. In some aneurisms of the arch of the aorta, the sac rises into the neck, so as closely to simulate a carotid aneurism, as in the annexed cut (Fig. 474). In such cases, Holmes suggests that the effect produced by carefully applied distal pressure may aid in the diagnosis. If, after a few hours, when the collateral circulation should be commencing to enlarge, the sac shows no signs of diminished tension, the case is very probably one of aortic aneurism. The principal affections of the neck, however, with which aneurism of the carotid

may be confounded, are varix of the internal jugular vein, enlarged lymphatic glands, abscesses, tumours, cysts, and pulsating bronchocele.

A *dilated artery doubled upon itself* may closely resemble an aneurism when situated at the root of the neck. Such a case is recorded by Coulson. It occurred in an old woman of 88. No treatment was adopted, and after death the supposed aneurism was found to be a reduplication of the common carotid surrounded by indurated cellular tissue.

In *varix* the tumour is always soft, does not pulsate expansively, and diminishes in size during a deep inspiration, and on compressing the vein on its distal side.

*Glandular tumours of the neck* are often very difficult to distinguish from aneurism, more particularly when the artery passes through the tumour, so that the whole mass distinctly moves at each pulsation. In these cases also

there may be an apparent diminution in the size of the tumour on compression, by the artery within it being emptied, or by the growth receding into some of the interspaces of the neck. But in the great majority of instances, the globular, oval, and nodulated feel of glandular swellings, and the possibility of raising them up and pushing them away from the vessel—which may best be done by feeling the carotid with the ends of the fingers of one hand, and then pressing upon the tumour with the other—will reveal the true nature of the case.

From *abscess of the neck* the diagnosis must be made on general principles. The coexistence of ill-defined hardness and of enlargement of the glands, of an inflamed state of the skin, the ready detection of fluctuation, and the absence of expansile pulsation in the tumour, will show that it is not aneurismal. It is of importance to observe also that an aneurism which fluctuates is always forcibly distended by strong pulsation, and can be materially diminished by pressure, neither of which circumstances can occur in abscess. But if abscess may be mistaken for aneurism, the converse also

Fig. 474.—Aneurism of the Summit of the Arch of the Aorta, simulating Carotid Aneurism.

holds good ; and an aneurism may be mistaken for abscess—a far more fatal error. And there is one variety of false aneurism, to which Liston specially invited attention, against which the Surgeon must be on his guard, on account of the many points of resemblance between it and aneurism : I mean the case in which an artery has given way into the sac of an abscess. In this case, fluctuation and pulsation will exist, although not perhaps of a distending kind. An important diagnostic mark, however, will be that the outline of an aneurism is distinctly defined and limited, while that of an abscess never is. Aneurism of the internal carotid has been found by Syme to simulate very closely *abscess of the tonsil*.

*Tumours* of various kinds—sarcomatous, fatty, and fibrous—may occur in the neck, and cause some little embarrassment in the diagnosis from aneurism ; thus Lisfranc, O'Reilly, and Kerr of Aberdeen have recorded instances in which the artery has been ligatured in such cases by mistake for aneurism. The diagnosis of such tumours as these must be made on ordinary principles. I have in several instances met with a small, hard, distinctly circumscribed tumour lying directly upon the carotid artery, and apparently connected with it, and receiving pulsation from it, usually produced by a fit of coughing or laughing. This tumour, with the true nature of which I am unacquainted, remains stationary, and does not require any operative interference.

The thyroid body is not unfrequently the seat of enlargements which have been mistaken for aneurism. These consist chiefly in a circumscribed enlargement of one lobe of the gland, which extends laterally over the common carotid, and receives pulsation from it. This kind of bronchocele may be diagnosed from aneurism by the communicated pulsation in it ceasing when it is raised from the artery. The most puzzling cases, and those in which mistakes may most easily be made, are instances of *pulsating bronchocele* in which these tumours have an active and independent pulsation or thrill. In these instances, however, there are three points that will almost invariably enable the Surgeon to make the diagnosis. Thus the tumour, although principally confined to one lateral lobe, always affects the isthmus more or less. Then again, in bronchocele, that portion of the tumour is most firmly fixed which stretches towards the mesial line ; whilst in carotid aneurism the firmest attachment is under the sterno-mastoid muscle. The third point of difference is that, on the patient's making an effort at deglutition, the enlarged thyroid body moves with the larynx and trachea. *Cysts in the thyroid body* are more common than pulsating bronchoceles, and sometimes equally difficult of diagnosis. Dupuytren has pointed out that, when these cysts are tapped, the pulsation often becomes stronger, and the fluid, which on first flowing is serous, may at last become pure arterial blood, so that the Surgeon may suspect that he has punctured an aneurism.

**TREATMENT.**—**Digital Compression** has been successfully employed for the treatment of carotid aneurism. A case of aneurism of the common carotid artery, cured by intermittent digital compression, has been recorded by Bouge of Lausanne. The patient was a man, aged 68. Compression was made by placing the thumb against the anterior edge of the sterno-mastoid and the next three fingers under the posterior edge of the muscle ; the artery was thus seized and compressed. This avoided any pressure on the pneumogastric nerve, which was supposed to be the cause of the pain

usually produced by attempts to compress the carotid. The compression was applied for seventeen days during seven or eight hours each day ; and at the end of the time the man was cured. In addition to this, Holmes has collected four successful cases by Sheppard, Kerr, Humphry, and Gay, and two unsuccessful ones by De Castro and Delore. The pressure should, if possible, be applied above the transverse process of the sixth cervical vertebra, so as to avoid compressing the vertebral artery at the same time.

**Ligature.**—Since Astley Cooper first ligatured the carotid, in 1805, the means on which the Surgeon almost always relies for the cure of aneurism of this vessel is deligation of the artery at a distance from the sac.

When the aneurism is so situated that a sufficient extent of healthy vessel exists between the sternum and the base of the tumour to admit of the application of a ligature, the Hunterian operation may be practised. If, however, the root or lower portion of the artery be so involved that there is no room to apply a proximal ligature, the distal operation may be performed.

**Ligature of the Common Carotid.**—The patient must be placed upon his back with the shoulders supported by a pillow, and the head allowed to fall backwards so as to put the sterno-mastoid slightly on the stretch. In the later stages of the operation, the head must be brought a little more forward to allow the muscle to be drawn outwards. If brought too much forward the artery becomes relaxed, and the difficulty in passing the needle is increased. When the Surgeon can choose the spot at which to ligature the artery, he usually selects the part of the vessel which bisects the angle formed by the anterior edge of the sterno-mastoid with the omo-hyoid muscle at the level of the cricoid cartilage. The course of the artery is marked by a line drawn from the sterno-clavicular articulation to a point midway between the mastoid process and the angle of the jaw. The practical guiding line during the operation is the anterior border of the sterno-mastoid, which forms the first rallying point. The artery is reached by making an incision about three inches in length in this line, the middle of the wound being opposite the cricoid cartilage. After dividing the skin, superficial fascia, and platysma, with the branches of the superficial cervical nerve, and the deep cervical fascia, the fibres of the sterno-mastoid come into view ; the inner border is easily found, and the muscle turned outwards. The second rallying point is the upper border of the anterior belly of the omo-hyoid. To bring this into view, the layer of cervical fascia forming the posterior part of the sheath of the sterno-mastoid must be dissected through, care being taken not to wound the descendens noni nerve which usually lies immediately beneath it. When the muscle is found, its upper border is pushed downwards with the handle of the scalpel, and held out of the way with a blunt hook, and the sheath of the vessels then comes into view. Crossing the sheath the middle thyroid vein may now be met with, and may, if necessary, be divided between two ligatures. The Surgeon now presses his finger backwards towards the bodies and transverse processes of the cervical vertebræ, and the artery will be felt rolling under the finger over the bone, and its exact position is thus easily ascertained. The vessel is enclosed in a sheath of cervical fascia common to it, the internal jugular vein, and the pneumogastric nerve. This sheath is divided into three compartments, and it is important to open the most internal of these, in which the artery lies, if possible without disturbing the others. To do this, the

common sheath must be opened well to the inner side, as the compartment for the vein is much larger than that for the artery, and occupies the greater part of the anterior aspect of the sheath which is exposed in the operation. After opening the common sheath, the special sheath of the areolar tissue surrounding the artery must be carefully divided until the white external coat comes into view. The needle is then passed from without inwards (Fig. 475), between the special sheath and the external coat, through the loose areolar tissue naturally found in this situation. If the vessel be properly cleaned, it is almost impossible to wound the vein or pick up the nerve. If, however, the wrong compartment of the common sheath be opened, or the special sheath not properly divided, either of these accidents may happen. Almost all the accidents which may happen in ligature of the carotid arise from one or two causes, either drifting too far outwards in the deeper parts of the incision, or not cleaning the vessel sufficiently before passing the needle. In cases of

Fig. 475. - Incision for Ligature of the Carotid Artery.

Fig. 476. - Diagram of the Right Common Carotid Artery at the seat of Ligature. *p.l.* platysma; *s.m.* sterno-mastoid, drawn to one side; *o.h.* omohyoid, drawn downwards and inwards; *s.h.* sterno-hyoid; *a.* the artery; *v.* internal jugular vein; *d.n.v.* descendens noni nerve. The pneumogastric is not seen, as it lies behind the vessels.

aneurism the difficulty is often increased by the proximity of the sac, and sometimes by inflammatory thickening of the sheath. In women the edge of the thyroid body may overlap the artery, and present a somewhat puzzling appearance when exposed. In performing the operation subcutaneous vessels are occasionally wounded, which may bleed rather freely; the small sterno-mastoid artery also may require to be ligatured. If the outer compartment of the sheath is accidentally opened, the jugular vein swells up so as to obscure the artery, but all difficulty from this source will cease if it be drawn aside by a retractor, or repressed by the assistant's finger. When this happens, it must not be forgotten that the septum of the common sheath, and the special sheath of the artery, have both to be divided before passing the needle. The pneumogastric nerve should never be seen, as it lies deeply behind the vessels.

After the operation the patient should be propped up in bed with the head forwards in order to prevent any strain upon the artery. Rest can be still more perfectly secured by applying a leather splint moulded before the operation to reach from the loins to the back of the head, and to overlap the shoulders. It can be put on immediately after the operation, and worn for the first two weeks.

*Ligature of the Carotid below the Omo-hyoid* becomes necessary if the aneurism have attained a very considerable size, extending low in the neck, and not leaving perhaps more than one inch of clear space above the clavicle. The operation is best performed by dividing the sternal head of the sternomastoid close to its origin. A V-shaped incision must be made, one limb of which corresponds to the lower two inches of the inner border of the sternomastoid, and the other to the inner two inches of the clavicle. The incisions are deepened till the muscle comes into view; the inner head is then divided and turned up in the V-shaped flap. The second rallying point is the edge of the sterno-hyoid. While searching for this, care must be taken not to wound the anterior jugular vein which crosses the muscle transversely on its way to join the external jugular. When the edge of the muscle is found, it may be drawn on one side with a spatula, or if necessary, notched. The sterno-thyroid scarcely requires division. The sheath of the vessels now comes into view, and must be cautiously opened, the Surgeon keeping carefully to the tracheal side so as to avoid the vein. There is usually a wide interval between the artery and the vein and nerve on the right side; on the left side more care is required, as the vein most commonly overlaps the artery.

After ligature of the common carotid the permanent collateral supply is not afforded by any of the branches of the corresponding vessel of the opposite side, but by the subclavian artery of the same side. In a case related by Porter, in which the right carotid had been tied, the subclavian and vertebral arteries on the same side were enlarged to at least double their natural size, and the chief communications outside the skull took place between the superior and inferior thyroid arteries, which were enlarged; whilst inside the cranium the vertebral took the place of the internal carotid. Immediately after the operation the blood may be so freely conveyed to the distal side of the vessel, by the free communication between the arteries of opposite sides, both within and without the cranium, that a speedy return of pulsation in the sac is of common occurrence. This condition, however, usually disappears after a time by the gradual consolidation of the tumour, and indeed may generally be looked upon as a favourable sign; being very seldom associated with those cerebral symptoms which, as will immediately be explained, commonly prove fatal after this operation. Occasionally the pulsation continues, and the tumour gradually increases in size in spite of the occlusion of the main trunk.

*Suppuration of the sac* is not of very uncommon occurrence after the ligature of the carotid for aneurism—sometimes even after so considerable an interval as eight months, as happened in a case related by Post. In the majority of these instances, the patient eventually does well; but death may result by the tumour pressing upon the pharynx and larynx, or by the occurrence of secondary hæmorrhage, which may take place either from the part to which the ligature has been applied, or from the suppurating sac. In the first

instance, it usually occurs before the healing of the wound, especially if union by first intention is not obtained ; in the second, it may happen at a considerably later period, even after many weeks. In a case under the care of H. Morris, suppuration took place round the sac fifteen weeks after ligature of the main trunk. Pus was let out by an incision, after which the tumour rapidly increased with return of pulsation. The aneurism was then laid open. It was found to have sprung from the external carotid, and the recurrent stream of blood was derived entirely from the branches of that vessel. The trunk above the sac, the facial, and the superior thyroid were ligatured, and the patient made a good recovery. As the suppuration is often due in all probability to the proximity of the wound and the ligature to the aneurism, it has been suggested that, in such cases, it might be safer to anticipate it by laying open the sac after the application of the ligature on the proximal side, and tying the vessel again on the distal side, thus performing a combination of Anel's and the old operation. It would appear, however, as if this were only substituting a certain evil for one that may very possibly be avoided. Besides these, which may be looked upon as the ordinary accidents following the application of a ligature for aneurism, deligation of the carotid artery occasionally gives rise to serious and even fatal disturbance of the circulation within the cranium.

**Effects on the Brain of Ligature of one or both Carotids.**—Many experiments have been made by Meyer, Jobert, and others, upon the lower animals, with the view of determining the effect produced on the brain by the ligature of the carotid arteries. But the deductions from these are of no value when applied to the human subject, for the simple reason (which appears to have been strangely overlooked), that in many of the lower animals on which the observations were made, as the dog and rabbit, the common carotid arteries are of secondary importance in the cerebral circulation, being destined principally for the supply of the external parts of the head—the brain deriving its chief supply from the vertebrales ; whilst in other animals, as the horse, the brain derives nearly the whole of its blood from the carotids, and but a very small quantity from the vertebrales. Hence, in one case the carotids may be ligatured without danger, whilst in the other their deligation is inevitably fatal. The statistics of ligature of the carotid in the human subject have been collected by Norris, Ehrmann, and others ; and more recently by Pilz of Breslau (*Archiv für klinische Chirurgie*, 1868), who has collected 600 cases of the operation, including 27 in which the artery was tied on both sides. The causes which led to the operation were, hæmorrhage, in 228 cases ; aneurism, in 87 ; erectile and other tumours, 142 ; extirpation of tumours, 71 ; cerebral affections (epilepsy, &c.), 34 ; and in 38 instances the distal operation was performed for aneurisms of the aorta and innominate artery. In the 228 cases of ligature for hæmorrhage, the presence of cerebral symptoms is noted in 69 out of 167—no information being given in regard to 61 ; and, in these 69 cases, death took place in 40. Excluding, however, these from calculation, inasmuch as the brain-disorder may have been in many due to the hæmorrhage rather than to the operation, we derive from Pilz's statistics the following table showing the proportional frequency of the occurrence of cerebral disease and of deaths from this cause.

TABLE OF LIGATURE OF CAROTID FOLLOWED BY CEREBRAL DISEASE.

CAUSES OF OPERATION.	NUMBER OF CASES.	CASES IN WHICH CEREBRAL AFFECTION ENSUED.	DEATHS FROM CEREBRAL DISEASE.	DEATHS FROM ALL CAUSES.	NO RECORD REGARDING CEREBRAL SYMPTOMS.
Aneurism	87	32	16	31	5
Erectile and other Tumours	142	32	20	49	3
Extirpation of Tumours	71	13	8	25	8
Cerebral Affections	34	8	—	1	3
Distal Operation	38	11	7	25	0
	372	96	51	131	19

By this it will be seen that the most common cause of death after ligature of the carotid is cerebral disease induced by the operation; and this result appears to have been relatively more frequent after the distal than after the Hunterian operation. If to these cases we add 14 in which the innominate artery was ligatured, we get a total of 386 cases of which 96 were attended with cerebral symptoms; or, as nearly as possible, 25 per cent.

We should naturally expect that, in those cases in which both vessels had been ligatured, there would be a greater tendency to cerebral disturbance than in those in which only one had been deligated. It would, however, appear that of twenty-seven instances in which the double operation was performed, death is recorded to have happened in but two cases from this cause; while in another, in which convulsions took place, a fatal result did not occur, and three other cases were attended with mere temporary disturbance of vision. In the only case—that of Mott—in which both carotids were ligatured simultaneously, with an interval of only a few minutes between the operations, coma and death resulted.

After a careful examination of this subject, I think we are warranted in coming to the following conclusions: 1. Ligature of one carotid artery is followed by cerebral disturbance in more than one-fourth of the cases, above one-half of which are fatal. 2. When the two carotids are ligatured *with an interval of some days or weeks*, the operation is not more frequently followed by cerebral disturbance than when only one is tied. 3. Pathological investigation has shown that, if the vessels be gradually and successively obliterated, the patient may live, although one carotid and one of the vertebral arteries have been occluded by disease and the other carotid ligatured, as in a case related by Rossi. 4. As in a case recorded by Davy, an individual may even live for a considerable time, though both carotids and both vertebrals be occluded—the cerebral circulation being maintained through the medium of the anastomoses of the inferior and superior thyroids and the deep cervical with the occipital artery. 5. The reason why more or less extensive obstruction by disease of the arteries leading to the brain may, as appears from pathological records, be unattended with cerebral disturbance, while this so frequently follows ligature, is (as has been pointed out by Pilz) that in the former case the obstruction is gradual, so that the collateral circulation has time to be established, while in the latter the interruption is sudden.

The cause of these *cerebral symptoms* is certainly the disturbance of the

cerebral circulation, induced by the ligature of the carotid. When a considerable portion of the supply of blood to the brain is suddenly cut off, two sets of symptoms may ensue—one *immediate*, the other *remote*. The immediate symptoms are those that generally result from functional disturbance of the brain, consequent upon too small a supply of arterial blood. They consist of syncope, trembling, twitches, giddiness, and impairment of sight. After this condition has been maintained for a few days, the nutrition of the organ becomes materially affected, and softening of the cerebral substance takes place, giving rise to a new and more serious set of symptoms indicative of this pathological condition, such as convulsions, hemiplegia, and death. In other cases congestion may come on, either by the interference with the return of blood through the jugular vein, or as a consequence of that venous turgidity which we commonly observe after the ligature of a main arterial trunk ; or perhaps coma may be induced by apoplectic effusion into a softened portion of the organ.

**Ligature of the Carotid on the Distal Side of the Sac.**—Aneurism of the carotid artery, occurring low in the neck, does not admit of the application of a ligature on the cardiac side of the tumour. What, then, is to be done in such a case as this ? Should it be left to the remote chance of a spontaneous cure, or should it be subjected to surgical interference ? Spontaneous cure in carotid aneurism has never yet, I believe, been met with. The Surgeon, therefore, must endeavour to treat the disease by ligature. Two plans of treatment are open to him—either to tie the innominate artery if the tumour be on the right side, or the carotid on the distal side of the tumour. The former alternative may fairly be set aside ; for not only are the cases in which it is possible to find room between the sternum and the sac extremely rare, but, even were such an instance to present itself, Surgeons would, I think, scarcely ever be justified in undertaking an operation which has so rarely succeeded (p. 190) ; we are consequently reduced to the alternative of ligaturing the artery on the distal side of the sac. But although this operation is the only alternative that presents itself, yet its application in practice is attended with serious difficulties ; for the Surgeon must be able to satisfy himself that it is actually an aneurism of the root of the carotid with which he has to do, and that it is not the trunk of the innominate or the arch of the aorta that is affected. The difficulty in doing this is far greater than would at first appear ; for, on examining the details of eight cases in which the distal operation was performed for supposed carotid aneurism, three must be excluded, as, after death, the tumour was found to arise from the aortic arch.

In every case the tumour, immediately on the ligature being tightened, underwent a considerable diminution in its bulk, with corrugation of the integuments covering it, and considerable subsidence in the force of its pulsations. In one case—that of Bush—respiration, which before the operation had been greatly embarrassed, became easy ; and in two others inflammation of the sac took place, being in one (that of Wardrop) unattended with bad consequences, and in the other (Demme's case) followed by death. It is not safe to deduce any general conclusion from so small a number of cases ; yet the result of these is so uniform, that I have no hesitation in stating it as my opinion that, whether we regard the principle on which this operation is founded, the amount of success which has hitherto attended it, the necessarily fatal result of these cases if left to themselves, or the absence of any other means that hold out a

reasonable hope of benefit, the Surgeon is justified in resorting to the ligature of the trunk of the common carotid on the distal side of the sac, in cases of aneurism limited to the root of that vessel.

#### ANEURISM OF THE EXTERNAL CAROTID.

The trunk of the external carotid is so short that it seldom becomes the seat of aneurism without involving at the same time the common artery at its bifurcation. It may, however, become aneurismal. The tumour, presenting the usual signs of aneurism, will be found situated under the angle of the jaw and above the level of the cricoid cartilage. From the important nature and

close proximity of the parts surrounding it, the pressure-effects are serious and early. By pressure on the hypoglossal nerve the muscles of the corresponding side of the tongue may be paralysed, so that when protruded the tongue is turned towards the affected side. Aphonia and dysphagia have been met with as early symptoms.

The treatment consists in ligature of the common carotid above the omo-hyoid. After this operation it may happen that pulsation continues faintly, or speedily returns in the sac, owing to the freedom of enlarged anastomoses. It has, therefore, been proposed by Morris to ligature the primary branches of the external carotid as well—a plan certainly difficult in execution and probably of doubtful utility.

In Fig. 477 is represented an aneurism of the external carotid for which the common carotid was ligatured by Christopher Heath. The artery is occluded above and below the ligature, and the aneurism is filled with laminated clot. Atrophy of the right half of the tongue had resulted from the pressure of the aneurism on the hypoglossal nerve. The patient, who was a woman twenty-three years of age, had

Fig. 477.—Aneurism of External Carotid cured by ligature of Common Carotid. A, point of application of ligature; B, internal carotid; C, external carotid; D, common trunk of lingual and facial.

suffered from several attacks of acute rheumatism. She died of cerebral embolism on the thirty-fifth day after the operation. The mitral and aortic valves were found to be extensively diseased.

**Ligature of the External Carotid Artery.**—Although this operation can rarely be required in the treatment of aneurism, it may conveniently be considered here. Amongst the various conditions in which ligature of the external carotid may be adopted in preference to that of the common trunk, may especially be mentioned hæmorrhage from its deep branches such as the internal maxillary (see Vol. I., p. 474), and as a preliminary stage in the removal of tumours in the regions supplied by it. An incision is made along the anterior border of the sterno-mastoid from a point opposite the angle of the

jaw to another opposite the middle of the thyroid cartilage. By dividing the superficial fascia and platysma, the anterior border of the sterno-mastoid is exposed and drawn outwards. The lower border of the posterior belly of the digastric is next defined and drawn upwards; below this muscle the hypoglossal nerve will be seen. The artery can now be exposed on a level with the great cornu of the hyoid bone, and a ligature applied to it between the origin of the superior thyroid and lingual branches. The needle should be passed from the outer side, and great care taken not to include the superior laryngeal nerve which lies behind the vessel. The proximity of large branches to the point of ligature interferes with the formation of the internal coagulum,

Figs. 478, 479.—Relations of External Carotid Artery at position of ligature. In Fig. 479 the veins have been removed.

a, common carotid artery; b, internal carotid; c, external carotid; d, lingual; e, superior thyroid; f, common facial vein; g, internal jugular vein; i, hypoglossal nerve; j, superior laryngeal nerve (dotted line); k, sterno-mastoid muscle (drawn aside); l, stylo-hyoid and digastric muscles; m, parotid gland; n, great cornu of hyoid bone.

but the risk of secondary hæmorrhage is small if an absorbable ligature be used and strict asepsis maintained. As an additional safeguard it has been recommended to tie the lingual and superior thyroid branches at the same time.

#### ANEURISM OF THE INTERNAL CAROTID.

The Internal Carotid Artery may be the seat of aneurism before or after it has entered the cavity of the skull. The symptoms of these two classes of aneurism differ necessarily in almost every respect.

**Extracranial Aneurism.**—When an aneurism affects the trunk of the internal carotid before its entrance into the skull, the symptoms do not materially differ from those of aneurism at the bifurcation, or of the upper part of the common carotid, except in one important respect, which was, I believe, first pointed out by Porter of Dublin—viz., the tendency of the tumour to extend inwards towards the pharynx, and to protrude into that cavity. The reason of this is obvious: when we consider the anatomical relations of the internal carotid artery, we at once see that its pharyngeal aspect is that which, if one may so term it, is the most superficial—nothing lying between the vessel and the mucous membrane except the thin superior constrictor, some lax areolar tissue, and the superior laryngeal nerve; whilst

externally there are interposed between it and the integument the layers of the cervical fascia, the margin of the sterno-mastoid, the digastric, stylo-hyoid and stylo-pharyngeus, and the styloid process, and above the digastric the parotid gland.

When, therefore, dilatation of the vessel takes place, it necessarily has a tendency to push forwards that part of its covering where it meets with least resistance; and, this being to the pharyngeal side, more or less prominence will be found in this cavity. In a case that occurred to Syme, this was especially well marked, the aneurism of the internal carotid simulating closely an abscess of the tonsil. In two cases related by Porter in the seventeenth volume of the *Dublin Journal of the Medical Sciences*, this was one of the most marked features: the "appearances of the tumour (as seen by the mouth) were most alarming; the pulsation could be distinctly seen, and the blood almost felt under the mucous membrane; it seemed ready to give way and burst into the mouth every moment."

**Treatment.**—The treatment of these cases does not differ from that of aneurisms connected with the carotid arteries, and seated at the upper part of the neck; but we are not in possession of a sufficient number of facts to enable us to determine with any degree of precision what the result of surgical interference in them is likely to be. If we could give an opinion from the limited number of cases at present before the profession, we should feel disposed not to entertain a very favourable opinion of the result of the Hunterian operation, as applied to aneurism of the internal carotid outside the skull. This is doubtless owing to the situation of the aneurism against the mucous membrane of the mouth, being such that the surrounding tissues do not exercise a sufficient amount of pressure against the sac after the ligature of the vessel to allow the efficient deposition of laminated coagulum, and consequent occlusion of the artery leading into it—circumstances which, in accordance with the principles that have been laid down in speaking of the Hunterian operation, are necessary to success.

#### INTRACRANIAL ANEURISM.

Aneurisms may arise from any of the intracranial arteries, though some are much more liable than others to this disease. Of 62 cases noted by W. Gall, the basilar artery was affected in 20 cases, and the middle cerebral in 15. In 8 of the remaining cases, the internal carotid was affected; and in 6 others the anterior cerebral artery was the seat of aneurism. The vertebral arteries and their branches were affected in 28 cases, and the carotids and their branches in 34.

**Causes.**—The causes of intracranial aneurism are very obscure. It might be supposed that the small size of the arteries within the skull would render them little liable to the occurrence of spontaneous aneurism, were it not that the anatomical characters and physiological relations of these vessels predispose considerably to the occurrence of this affection; there being no other set of arteries in the body of the same size as those within the skull in which spontaneous aneurism so frequently occurs. This can be accounted for only by the thinness of their coats and the want of an external fibrous sheath rendering them unable to support the increased tension to which they are occasionally subjected in consequence of the alteration in pressure of the cerebral circula-

tion at different periods, the result of some variation in the relative quantities of the different fluids within the skull, or of determination of blood to the brain. This would be the case more particularly if their elasticity had already been impaired by degeneration or syphilitic disease of their coats. Thus, according to Gull, of 58 cases in which the patient's age is given, only 12 cases appeared in persons under twenty-five, five of the patients being under twenty; of the remaining 46 cases, 13 occurred in persons under forty; of the remaining 33, 22 were met with between forty and sixty, and 4 in persons above sixty. Of the 58 cases, 35 were males, and 23 females. Church believes that, in the young, intracranial aneurism is due to embolism.

The exciting cause of the disease is most commonly involved in obscurity: sometimes it may be traced to a blow on the head, to a fall or concussion, or to excess in drinking; but more frequently the symptoms manifest themselves suddenly, without being in any way attributable to such external influences, and occur in vigorous and apparently healthy persons.

**Pathology.**—Intracranial aneurisms are almost always formed by the uniform dilatation of a limited portion of the artery—the sacculated variety being rarely met with. In the museum of University College there are, however, two specimens of sacculated aneurisms of the cerebral arteries. The coats of the arteries in this situation being very thin, and unprovided with any external fibrous sheath, rupture of the vessel is more common than partial dilatation, when one portion only of the circumference is dilated. Occasionally, the dilatation is fusiform, extending over some length of the artery: this form is probably confined to the basilar artery (Fig. 480).

The disease would appear to be of slow growth, and the sac sometimes becomes filled with laminated coagula so completely as to occlude the artery from which it springs.

Gowers arranges the intracranial arteries in the following order as far as their liability to be the seat of aneurism is concerned: middle cerebral, basilar, internal carotid, anterior cerebral, posterior communicating, anterior communicating, vertebral, posterior cerebral, inferior cerebellar. Aneurisms in this situation is sometimes considerable: thus, in a case of aneurism of the basilar artery, which occurred some years ago at University College Hospital, the tumour was nearly as large as a walnut; in another case, it somewhat exceeded this size. R. W. Smith, in the *Dublin Journal of the Medical Sciences*, vol. xxv., mentions a case of multilocular aneurism of the left posterior cerebral artery as large as a small apple; and Serres, as large as a hen's egg. On the other hand, they occasionally prove fatal by rupture while still of very small size—not larger than a pea or a nut.

It is seldom that more than one of the arteries of the brain suffer aneurismal

Fig. 480.—Fusiform Aneurism of Basilar Artery laid open.

dilatation. In the Museum of the College of Surgeons, however, there are preparations of aneurismal dilatation of both internal carotid arteries.

A case occurred in University College Hospital under the care of A. T. Thomson, in which a somewhat similar condition existed. A man, forty-nine years of age, had fallen on his head some months before admission into the Hospital. Since then he had been garrulous, silly, and very irritable—becoming readily intoxicated. He suddenly became comatose, with vomiting and laborious breathing; he could close both eyes, but the right pupil was dilated; the left side was paralysed. He was treated for apoplexy, and became slightly better, but died in ten days from the first attack. An aneurism a little larger than a hazel-nut was found on the trunk of the right carotid, where it gave off the middle cerebral, and another small one on the course of that artery. There was a globular aneurism on the corresponding artery of the opposite side; the basilar artery was thickened, white, and opaque, as were also the other larger arteries of the brain; there was softening of both anterior cerebral lobes, especially the right.

**Pressure-Effects.**—The pressure exercised by an aneurism situated within the skull is always chiefly directed against the yielding cerebral substance, which is often extensively disorganised; the bones of the skull frequently escape, and seldom suffer much. Absorption of the subjacent bone, however, sometimes takes place to a limited extent: thus, in one case (Moore's) the body of the sphenoid bone was indented and partially absorbed.

The parts compressed in each case will vary according to the situation of the tumour. But the structures that principally suffer are necessarily those seated at the base of the brain, and forming the floor of the lateral ventricles. In Moore's case, one of the optic nerves was flattened; the lamina perforata, the roots of the olfactory tract, the anterior part of the corpus striatum, and a considerable quantity of the neighbouring white matter of the anterior lobe, were destroyed. In a case recorded by Lager, the facial nerve of the right side was paralysed from this cause. In R. W. Smith's case, the floor of the third ventricle, the tuber cinereum, and the origins of the optic and olfactory nerves, suffered; the optic nerve of the opposite side was flattened and softened.

Besides the changes that take place in the cerebral substance as the result of pressure, important lesions may be met with as the effect of the interference of the aneurism with the circulation in and nutrition of the cerebral hemispheres. Thus, in the case of aneurism of both internal carotids that has already been referred to as occurring at University College Hospital, there was white softening of both the anterior cerebral lobes; and this lesion was most marked on the side that corresponded to the larger aneurism, and where consequently, it may be supposed, the greater amount of obstruction to the circulation existed.

**Symptoms.**—The symptoms of aneurism within the skull are extremely equivocal; and, indeed, an aneurism of large size may exist at the base of the brain without occasioning any symptoms whatever. An interesting instance of this occurred at University College Hospital in 1848. A man, thirty-seven years of age, died of pulmonary apoplexy and chronic pneumonia of the left lung, consequent upon the pressure of an aneurism of the commencement of the descending aorta on the pulmonary veins. On *post-mortem* examination an aneurism of the basilar artery as large as a hazel-nut was found, which had

caused no head symptoms; the sac was very thin, and there was much atheromatous degeneration in the vertebral arteries.

Not unfrequently no symptoms occur until the rupture of the aneurism causes fatal cerebral apoplexy. In many cases, however, definite local symptoms are produced by the pressure of the aneurism on the important structures at the base of the brain. Pain is a very variable symptom, both as regards its character and its position. It may be diffused, or may occupy a fixed point; it may be continuous or intermitting; it may be increased by movement, or accompanied by peculiar sensations, as of pulsation or of opening and shutting the top of the head.

The sight and hearing are often impaired. Dimness of sight, dilatation of one or both pupils, photophobia, diplopia, and loss of vision have been noticed in several of the cases recorded. Gowers states that intracranial aneurisms, even of large size, are not as a rule accompanied by any associated ocular changes. Nor do they often cause consecutive changes, unless their position is such as to press upon the optic nerves; there is then loss of vision with atrophy of the nerve recognizable by the ophthalmoscope. If the aneurism press on the cavernous sinus, there may be some fulness of the retinal veins, but this is usually only temporary, the pressure being relieved by the free communication between the ophthalmic and facial veins. Optic neuritis is rare as the result of intracranial aneurisms. Ptosis has been met with from pressure on the third nerve by aneurism of the posterior communicating artery. Buzzing noises in the ears and deafness are not uncommon symptoms. The patient rarely loses the power of articulation and of deglutition; impairment of these functions, however, has been met with. There may be paralysis of the side of the face, or complete hemiplegia; or fits and epileptiform convulsions may occur. The mental condition may undergo changes indicative of chronic disease of the brain. There may be depression of spirits, listlessness, or, as was noticed in the case above related, the temper may become irritable, and the patient be garrulous or silly. Insanity has been noticed in one case. As is commonly the case in cerebral affections, the gastric functions are often impaired.

In some cases the presence of aneurism has been detected by a loud rough or "whizzing" noise heard on the application of a stethoscope over one side of the head, and, perhaps, audible to the patient. This sign, however, exists in but few cases; but when it does occur, it is unquestionably the most pathognomonic of all. I am not aware that it has been met with in any form of cerebral disease except intracranial aneurism.

It will thus be seen that, with the exception of the whizzing noise, no special signs are afforded by aneurisms within the skull, which will enable us to distinguish between the symptoms occasioned by their presence and those of other tumours of the brain, and of organic cerebral disease. Very frequently no premonitory symptoms manifest themselves; the patient being suddenly seized when apparently in good health, with apoplexy, which terminates rapidly in death.

**Causes of Death.**—The most frequent cause of death in these cases is the *sudden rupture of the sac* and extravasation of blood into the cavity of the arachnoid and the meshes of the pia mater at the base of the brain, or into the lateral ventricles—either from the aneurism projecting into them and there giving way, or rupturing into the cavities by breaking down the intervening

cerebral substance (Figs. 481, 482). When this mode of termination occurs, there are occasionally no premonitory symptoms of impending danger; the patient, when apparently in good health, being struck down by an attack of apoplexy which is speedily fatal. More frequently a series of those symptoms that have already been mentioned as attending many cases of this disease, precede the fatal event for a longer or shorter time. When rupture of the sac and extravasation of blood take place, death is inevitable; at least, I am not acquainted with any case in which signs of old extravasation have been found after death.

Death from rupture of the sac appears to be most frequent in younger subjects. In the later period of life, aneurism is commonly associated with atheromatous disease of the vessels generally, which may cause death by softening and effusion of blood. According to Gull, of 20 cases occurring in persons under thirty-five years of age, 16 (or 80 per cent.) were fatal from rupture of

Fig. 481.—Aneurism of the Left Internal Carotid, investing into Lateral Ventricle. View of Aneurism from above, projecting into Ventricle.

Fig. 482.—View of the same Aneurism from below, imbedded in substance of Hemisphere.

the sac; while in 37 cases over thirty-five, death occurred from this cause in only 14, or 38 per cent.

In other cases death may result from *softening of the substance of the brain*, due to the obstruction offered to the passage of the blood through the aneurismal vessel. In the case of aneurism of both carotids, already mentioned as having occurred at University College Hospital, this was the case; both anterior cerebral lobes were affected with white softening, and this condition was especially observable on that side on which the aneurism was larger.

**Treatment.**—In the treatment of intracranial aneurism there is usually little to be done, the nature of the case not being sufficiently obvious in the majority of instances to justify active measures. The general treatment recommended for aneurisms elsewhere should certainly be adopted, such as rest, appropriate dieting and the administration of iodide of potassium. Should, however, the loud rough whizz be distinctly audible over one side of the head, more especially about the base of the skull, or by application of the

stethoscope to the mastoid process, and should symptoms of cerebral compression begin to manifest themselves, ligature of the carotid artery on the affected side may with propriety be practised. This was done successfully in a most interesting and instructive case of intracranial aneurism by Coe of Bristol ; and unsuccessfully by Berkeley Hill, in one at University College Hospital, in which death took place from hæmorrhage from the seat of ligature.

#### INTRAORBITAL ANEURISM.

"Intraorbital aneurisms" were for a long time considered by Surgeons to be of the nature of erectile tumours ; but the erroneousness of this opinion was pointed out by Busk, and subsequently by Nunneley, who showed that, except in those very rare cases in which a pulsating tumour of the orbit is congenital, or has appeared shortly after birth, or is associated with nævoid tissue developed in the eyelids, it must be looked upon as being due in the vast majority of cases to the presence of an aneurism or aneurismal varix at the back of the orbit. These views have been fully confirmed by Rivington in his exhaustive paper founded on 73 recorded cases of pulsating tumour of the orbit collected from various sources, and including one very interesting case of his own. The vessel affected seems to be in some instances the ophthalmic artery itself ; in other instances it would appear that the tumour is developed within the cranium, springing from the carotid artery, the ophthalmic being but secondarily affected. Delens of Paris has recorded three cases verified by *post-mortem* examination, in which the symptoms arose from an arterio-venous aneurism affecting the carotid artery in the cavernous sinus.

**Causes.**—The causes of intraorbital aneurism are in some cases very obscure ; in others, the condition evidently has originated from a blow upon the head. In the first class of cases, where the disease has been of spontaneous origin, the patient has suddenly felt a crack or snap in the orbit, like the "crack of a whip," or the "snap of a gun," and the disease has then developed gradually. In the traumatic cases, the blow upon the head has usually been severe, attended in some instances with symptoms of fracture of the anterior part of the base of the skull. In several cases it has arisen from penetrating wounds of the orbit caused by sticks or small shot.

Of the 73 cases collected by Rivington, 32 were idiopathic and 41 traumatic. Of the idiopathic cases two were congenital, probably genuine specimens of cirroid aneurism ; the mean age of the rest was 43, the oldest being 69. The mean age of the traumatic cases was between 30 and 31, the extremes being 11 and 72. The spontaneous cases were most commonly in women ; thus, of 30 cases in which the sex is recorded, 21 were females. The traumatic form is most common in men, the number being 31 males to 10 females. Amongst the idiopathic cases 15 occurred on the right side, 13 on the left, and 2 on both sides ; of 40 traumatic cases, 10 were on the right, 27 on the left, and 3 on both.

**Symptoms.**—The first sensation experienced is, in spontaneous cases, that of a loud snap or crack in the orbit or head. This is followed by congestion of the conjunctiva, difficulty in opening the eyelids, a feeling of tension, and in some instances severe pain in and around the orbit. Loud whizzing bewildering noises are experienced in the head, and are much increased on stooping or lying down. In traumatic cases, a persistence of congestion of the conjunctiva

with redness and some cedema of the eyelids, and the occurrence of noises in the head, are usually the first indications of the mischief that has occurred. In all cases, after a time, the eyeball becomes unduly prominent, and pulsation of a thrilling vibratory character can be felt in the orbit; on the application of the ear, a loud whizzing bruit is heard, which extends widely over the side of the head. The eyeball itself eventually falls into a state of chronic congestion; chemosis occurs, the cornea becomes opalescent, the aqueous humour turbid, and sight is impaired or lost. The bruit and pulsation are diminished or cease on compressing the carotid artery of the side affected.

**Pathology.**—The essential features of so-called intraorbital aneurism, or pulsating tumour of the orbit, may arise from more than one pathological condition. Rivington has collected 14 fatal cases in which the diseased parts were examined after death. In one only (Guthrie) was an aneurism found in the orbit. In this case the disease was double, and there was a circumscribed aneurism on each ophthalmic artery. In four cases no arterial disease was found: in one of these (Oettingen) there was obliteration of some of the veins of the orbit from old inflammatory mischief, in the other three (Bowman, Aubrey, and Morton,) there was obstruction to the passage of blood from the orbit through thrombosis of the intracranial sinuses. In one (Nunneley) there was a circumscribed aneurism of the ophthalmic artery before it entered the orbit; in three (Baron, Gendrin, and Nunneley) rupture of an aneurism of the internal carotid into the cavernous sinus was found; in one (Wecker) simple dilatation of the carotid in the cavernous sinus was the cause of the disease; and in the remaining four, an aneurismal varix of the carotid artery and cavernous sinus was found. These four were all the result of injury, one arising from a direct wound from the point of an umbrella thrust into the opposite orbit, and the others from severe blows on the head, probably accompanied by fracture. No case of aneurism by anastomosis of the orbit has been demonstrated by *post-mortem* examination, but there is strong reason to believe that two cases of congenital origin which have been recorded were of this nature. The earlier observers supposed all cases to be due to aneurism by anastomosis. The fallacy of this opinion was first pointed out by Busk, who referred the symptoms to a rupture of the ophthalmic artery and the development of a circumscribed traumatic aneurism of that vessel; this also has not been demonstrated by *post-mortem* observation. Nunneley doubted the correctness of this view, and referred the symptoms, in some cases, to a peculiar vascular condition of the parts, dependent more upon an affection of the veins than of the arteries, and somewhat analogous to what takes place in the exophthalmos of bronchocele. He pointed out also that although in other cases an aneurism exists, it is not in the orbit, but behind it in the cavernous sinus. In these latter cases he showed that the prominence of the eyeball is due to distension of the veins of the orbit from obstruction to the return of blood, and the pulsation is communicated to these distended veins by the aneurism in the cavernous sinus. This view is fully confirmed by the *post-mortem* records quoted above. In those cases in which nothing beyond obstruction to the return of blood through the cavernous sinus and consequent dilatation of the orbital veins has been found, the cause of the pulsation is not so evident. In other cases it is perhaps possible that some derangement of the vaso-motor influence of the sympathetic may really

occasion the symptoms of increased vascular activity that are so characteristic of the disease.

The secondary phenomena that are observed in these cases, such as congestion of the eyelids, of the palpebral and ocular conjunctivæ, amounting even to chemosis in many cases, and the muddiness of the aqueous humour and lens, are doubtless due to an interference with the return of blood from these parts through the ophthalmic vein, and to the consequent congestion of the smaller vessels and effusion of serum. The protrusion of the eye-ball is due to the vascular tumour, whatever its precise nature may be, and the derangement in vision to an alteration in the axis of the eye consequent on this extrusion. It is remarkable that the bruit in these cases should be so loud, not only to the patient's own senses, but to the ear of the Surgeon; and this can be accounted for only by the proximity of the cranial bones, which may act as conductors of sound.

**Diagnosis.**—The *Diagnosis* of pulsating tumour is sufficiently easy, but it is just as difficult to determine accurately the cause of the disease. It is probable that nearly all the traumatic cases are due to aneurismal varix of the carotid artery and cavernous sinus. The sudden onset of the disease with a crack or snap in idiopathic cases would lead to a presumption that a small aneurism of the carotid had given way into the sinus. Congenital cases are probably aneurisms by anastomosis. Beyond this, accurate diagnosis of the pathological condition is hardly possible. The disease most likely to be mistaken for an intraorbital aneurism is a pulsating sarcoma of the bones of the orbit. In this, however, the pulsation is less expansile and the peculiar harsh bruit is wanting.

**Prognosis.**—I think it is still doubtful what would happen in a large number of these cases, if the disease were left to itself without operation. It might be supposed that it would probably have a fatal termination; that rupture would take place either into the cranial cavity or externally, and that sudden death would occur. That this has occasionally happened is proved by recorded cases, but it is by no means a necessary consequence of the disease. Spontaneous cure appears to take place in some cases: thus I have seen a gentleman about 44 years of age, who, in consequence of a fall on the head a few months previously presented the characteristic symptoms of intraorbital aneurism. Ligature of the carotid artery was recommended, but the patient would not consent to the operation, and fourteen months later the symptoms of the disease had to a great extent disappeared. A grave prognosis should not be given hastily, as it is only by watching the case that a correct conclusion can be arrived at. If the protrusion of the eye-ball continues to increase, and the globe itself begins to suffer, and vision is lost, the prognosis becomes grave and the case is one requiring surgical treatment. If there is no increase of the symptoms after some months, the patient may be left to nature unless the annoyance of the disease is great.

**Treatment.**—The occasional occurrence of spontaneous cure, the uncertainty in which we often are as to the real nature of the disease, and the certainty that in some instances at least there is no true aneurismal tumour, would justify the Surgeon in having recourse to medical treatment, aided by digital compression of the carotid, and, perhaps, the application of ice to the forehead, before proceeding to operate. That these means are occasionally successful, there can be no doubt. Gioppi, of Padua, has recorded a case in

which an intraorbital aneurism of great severity was cured by intermittent digital compression. The compression was kept up for periods of a minute or two with frequent intervals; pressure continued for more than one minute caused fainting. The disease was cured in four days. Vanzetti and Sarramuzza have published another case, in which intermittent digital compression was kept up for five minutes at a time. The case was completely cured by compression during seven hours and twenty minutes, spread over eighteen days.

Among the cases collected by Rivington were 16, including those just mentioned, in which *digital compression of the common carotid* was adopted. Of these, 5 were idiopathic and 11 traumatic. Two of the former and one of the latter were cured; in the rest no benefit resulted from the treatment. *Instrumental compression* was tried in four cases without result. *Galvanopuncture* was tried twice; once it failed and once it was fatal. *Coagulating injections* were used in four cases, in all of which the disease was traumatic. The substance used was perchloride of iron in three cases, two of which were cured and one derived no benefit. In the fourth case a solution of lactate of iron was injected and the patient was cured. In spite of this success the injection of coagulating fluids into a dilated vein in which it is impossible temporarily to arrest the flow of blood, can hardly be regarded as a safe proceeding.

*Ligature of the common carotid* of the affected side has been highly successful. Rivington has collected 54 cases in which it was performed: 21 were idiopathic, 32 traumatic, whilst the nature of one was not known.

Of the 21 idiopathic cases 4 died and 17 recovered; of these 17, 13 were cured, in 9 vision was restored, in 3 it was not regained, and in the others the effect in this respect is not mentioned. Three cases were benefited by the operation, whilst in one the relief was temporary and the eye-ball and tumour were subsequently removed. Of the 32 traumatic cases, 5 died and 27 recovered. Of these 27, 17 were cured, 1 by subsequent injection. Vision was not regained in 6. In 5 the operation failed, and 2 of these were subsequently cured by ligature of the opposite artery. Four were partially cured, and one relapsed after apparent cure.

The evidence of recorded cases thus seems strongly in favour of the treatment of this disease by ligature of the common carotid artery when simple medical treatment and compression have failed to produce a decided impression.

In a very interesting case which I saw in Velpeau's wards in 1839, both orbits were affected; and as pressure on the right carotid arrested the pulsation and bruit in both, that artery was tied. But though the disease was cured in the left orbit by this operation, and temporarily arrested in the right, it reappeared in the latter situation, and was eventually cured there by the ligature of the left carotid.

#### ANEURISM OF THE SUBCLAVIAN ARTERY.

Aneurisms of the Subclavian occur in order of frequency between those of the carotid and of the innominate arteries. They are most often met with on the right side, in the proportion of about three to one; and this would appear to be in a great measure dependent on their being occasioned by

direct violence, or by repeated or prolonged exertion of the arm : thus they commonly occur from falls, blows upon the shoulder, or excessive fatigue of this extremity. From the fact of the aneurisms arising from external violence, we should expect to meet with them most frequently in males, and this we do in a remarkable manner. Of 120 cases collected by Poland, only 11 occurred in females, and in 4 of these instances the disease resulted from injury ; in 2 cases, both arteries were affected. The disease may be seated in any part of the vessel on the right side, though most commonly the artery is not dilated until after it has passed beyond the anterior scalenus. On the left side aneurism never occurs before the artery has emerged from the thorax ; and then, as on the right, it most commonly happens in the third part of the vessel. Subclavian aneurism may occur at any age above 21. It is most common in middle life ; and, according to Poland, is three times more frequent in England than in any other country.

**Symptoms.**—An aneurism of the subclavian artery is characterised by a pulsating compressible tumour of an elongated or ovoid shape, situated at the base of the posterior triangle of the neck, immediately above the clavicle. If it be small, it will disappear behind this bone on the shoulder being raised ; as it increases in size, it fills up the whole of the space above the clavicle between the sterno-mastoid and the trapezius, often attaining a very considerable bulk. In consequence of the pressure which it exercises on the brachial plexus of nerves there is pain, often attended with numbness, and extending down the arm and fingers, usually with some weakness of these parts. In some instances there is a spasmodic affection of the diaphragm, owing to irritation of the phrenic nerve. The external jugular vein is commonly distended and varicose ; cedema of the hand and arm may be present. The tumour does not increase rapidly in size, owing to its being tightly compressed by the surrounding parts ; and, as the disease never extends inwards, it does not interfere with the trachea or oesophagus. In some cases it has been known to extend downwards and backwards, so as to implicate the pleura and the summit of the lung.

**Diagnosis.**—This is usually easy, although an enlarged gland or chronic abscess lying over the third part of the artery may at first sight be mistaken for an aneurism of the vessel. When the disease affects the first part of the artery it may present features closely resembling those of an aneurism of the innominate or of the root of the carotid. Under these circumstances the condition of the pulse in the branches of the carotid may aid the diagnosis, for it is unlikely to be affected when the aneurism is limited to the subclavian. Mayo mentions a case in which an exostosis of the first rib pushed forward the subclavian artery in such a way as to cause it to simulate an aneurism, and eventually to arrest the pulsation in it.

**Results.**—As a subclavian aneurism increases in size, it may become diffused, and burst either externally or into the pleural sac. A spontaneous cure has more frequently occurred in this than in any other external aneurism.

**Treatment.**—The treatment of subclavian aneurism is in the highest degree unsatisfactory.

A fair trial should, in all cases, be given to complete rest and restricted diet according to the plan described on page 118. In one recorded case a subclavian aneurism was cured by Valsalva's treatment in eighteen months. This constitutional treatment may be supplemented in suitable cases by applying

*direct pressure* to the sac itself; this can be done by means of a weight, or by a leaden or leathern cap moulded to the swelling.

*Compression on the cardiac side* can be employed only when the artery rises high enough in the neck to admit of pressure being applied between the scalenus and the sac. Such a combination of irregular anatomical distribution with aneurism must of necessity be excessively rare; but in one case in which it occurred, Poland succeeded in effecting a cure by digital compression kept up for ninety-six hours. The tumour was then smaller and harder, but still pulsated. The patient left the Hospital, and, at the end of a month, the tumour was found to have become solid, and had ceased to pulsate. The number of cases in which compression is possible may perhaps be increased by performing the operation under prolonged anaesthesia.

*Compression on the distal side* could be effected only when the artery crosses the first rib, and consequently would be available only in those rare cases in which the aneurism springs from the first part of the vessel.

*Manipulation*, as recommended by Fergusson, deserves a further trial; of the few instances in which it has been employed it was successful in Little's case and partially so in Fergusson's case.

*Galvano-puncture* and *Acupuncture* are also available methods of treatment, and might be combined, when practicable, with distal compression. Galvano-puncture has been successfully employed by Abeille and acupuncture by Macewen.

*Ligature of the innominate, and of the subclavian itself*, internal to, behind, and beyond the scalenus anticus, has been practised for the cure of this form of aneurism; it has likewise been proposed to apply the distal operation to the treatment of this disease, and to amputate at the shoulder-joint.

When an aneurism is situated on the right subclavian artery on the tracheal side of the scalenus, the flow of blood through it can be arrested only by the ligature of the innominate artery. When it is situated beyond the scalenus, or even behind it, ligature of the subclavian has been practised in the first part of its course before it reaches this muscle. For subclavian aneurism on the left side, in these situations, the proximal ligature would not be practicable.

Let us now proceed to examine the results that have attended these operative procedures.

**Ligature of the Innominate.**—The innominate artery, as may be seen by the accompanying table, has been ligatured at least twenty-two times.

CASES OF LIGATURE OF INNOMINATE ARTERY.

OPERATOR.	SEX.	AGE.	NATURE OF DISEASE.	RESULT.	REMARKS.
1. MOTT.	m.	57	Subclavian aneurism.	Died on 26th day.	Tied an inch below bifurcation. Ligature separated in fourteen days. Hemorrhage on 23rd day, stopped by pressure: recurred on 26th.
2. GRÄFE.	m.	abt. 30	Subclavian aneurism.	Died on 68th day.	Ligature separated in fourteen days. Hemorrhage after separation of ligature arrested by cold and pressure, and did not recur. Suppuration of sac: incision. Hemoptysis and fever. Death without further hemorrhage. Artery safely occluded.

CASES OF LIGATURE OF INNOMINATE ARTERY—(continued).

OPERATOR.	SEX.	AGE.	NATURE OF DISEASE.	RESULT.	REMARKS.
3. HALL.	m.	52	Subclavian aneurism.	Died on 5th day.	Artery was diseased and gave way. Bleeding arrested by plug : death from other causes.
4. A SURGEON IN PARIS.	...	...	...	Died.	Case referred to by Dupuytren.
5. NORMAN.	m.	...	Subclavian aneurism.	Died.	Died of pericarditis sixty hours after operation.
6. BLAND.	m.	31	Subclavian aneurism.	Died on 18th day.	Hæmorrhage from distal side came on on the 17th and 18th days. Ligature applied to upper portion of artery.
7. LIZARS.	m.	30	Subclavian aneurism.	Died on 21st day.	Ligature separated on 17th day. Hæmorrhage on 19th. Pleurisy of right side.
8. HUTIN.	m.	26	Hæmorrhage from axilla after ligature of subclavian.	Died in 12 hours.	Punctured wound in axilla, for which subclavian was tied ; secondary hæmorrhage, and then innominate tied.
9. ARENDT.	m.	36	Subclavian aneurism.	Died on 8th day.	Inflammation of lung, pleura, and aneurismal sac.
10. COOPER. (San Francisco.)	m.	...	Subclavian and carotid aneurism.	Died on 9th day.	Upper end of sternum and inner end of clavicle removed. Dyspnoea and retention of urine : pus in the right kidney.
11. COOPER. (Do.)	m.	...	Subclavian and carotid aneurism.	Died on 34th day.	Bones removed as in previous case. Patient was apparently doing well, when secondary hæmorrhage appeared. Immediate cause of death, hæmorrhage, in consequence of removal of bandages by patient.
12. GORE. (Bath.)	m.	52	Subclavian and axillary aneurism.	Died on 17th day.	Artery partially cut through by ligature. Cardiac extremity not contracted, but partially plugged with dark coagulum. Inflammation of subclavian vein (left). Pus in anterior mediastinum. Aneurism contracted and filled with coagulum.
13. SMYTH. (New Orleans.)	m.	32	Subclavian aneurism.	Recovery.	Ligature applied to innominate a quarter of an inch below bifurcation, and at same time to carotid one inch above origin. Hæmorrhage on 15th, 33rd, and 51st days, arrested by pouringshot into the wound. Ligature of right vertebral on 54th day. Tumour returned ten years afterwards and proved fatal.
14. BICKERSTETH. (Liverpool.)	m.	40	Subclavian aneurism.	Died on 6th day.	Direct compression tried on the artery for two days. Then ligatured above and below the spot where compression had been applied. Death from hæmorrhage from the distal side.
15. O'GRADY. (Dublin.)	...	...	Subclavian aneurism.	Death next day.	Carotid also tied. Apoplectic symptoms.

## CASES OF LIGATURE OF INNOMINATE ARTERY—(continued).

OPERATOR.	SEX.	AGE.	NATURE OF DISEASE.	RESULT.	REMARKS.
16. W. THOMSON. (Dublin.)	m.	49	Subclavian aneurism.	Died on 42nd day.	Secondary hæmorrhage 30th and 39th days. The hæmorrhage came from an opening in the artery, the result of ulceration. It was one quarter of an inch above the seat of ligature. An ox-aorta ligature was used. No trace of it was found at the <i>post-mortem</i> .
17. BENNETT MAY.	m.	30	Subclavian aneurism.	Died on 18th day.	Secondary hæmorrhage from ulceration opposite the knot of the ligature. Twisted strands of catgut used after breaking of an ox-aorta ligature; coats not divided.
18. BANKS.	m.	50	Subclavian aneurism.	Recovery.	Kangaroo-tendon ligature; coats not divided. Common carotid also tied. Pulsation returned and aneurism increased. Ligature of first part of subclavian 67 days later. Death from secondary hæmorrhage on 37th day. Aneurism had become small and hard.
19. DURANTE. (Rome.)	...	...	Subclavian aneurism.	Died on 15th day.	The carotid and vertebral were also tied. Hæmorrhage occurred on 12th and 15th. Death from cerebral embolism. The aneurism was collapsed and contained coagula of varying consistence.
20. TWYNAM.	f.	18	Subclavian aneurism.	Died in 18 hours.	The aneurism was traumatic. Silk ligature applied through median incision. Carotid also tied. Death from cerebral symptomata.
21. JACOBSON.	m.	48	Subclavian and axillary aneurism.	Death on 16th day.	Ox-aorta ligature; coats not divided. Carotid also tied. Death from broncho-pneumonia and exhaustion. The aneurism was almost full of jelly-like coagulum.
22. COPPINGER. (Dublin.)	m.	53	Subclavian and axillary aneurism.	Recovery.	Soft silk ligature applied through median incision. Carotid divided between two ligatures. Sixteen months after the operation the patient was in perfect health, and "the aneurism was represented only by a small movable and hard filbert-sized tumour."

As will be seen from the above table, there are only three recorded cases of recovery after ligature of the innominate artery. In four other instances the operation has been commenced, but abandoned owing to unforeseen difficulties, and this by some of the most skilful operators that their respective countries can boast of.

Although, in reasoning on the propriety of performing an operation, it is not in general worth while to take into consideration the difficulties that the Surgeon may encounter, provided the operation be practicable; yet, when we consider that this operation has been left unfinished in several cases by Surgeons who were well able to accomplish whatever was within the limits of

possibility, we may well hesitate to undertake so serious a proceeding. The difficulties do not consist merely in the position and relations of the vessel, but rather in the condition in which the artery and the adjacent structures may be found after the vessel is exposed. Thus, in Porter's case, the aneurism occupied the whole of the inferior posterior triangle of the neck ; as no pulsation was traceable in the vessels beyond the aneurism, it was useless to attempt ligature on the distal side. On exposing the innominate it was found to be so diseased that it was not thought desirable to pass the ligature round it. After the operation, however, the pulsation of the tumour gradually diminished, and at last ceased, its bulk also becoming less. In Key's case, in which it was impracticable to pass the ligature, it was found after death that the innominate was dilated immediately after its origin into an oblong tumour, which occupied the whole of the artery. It is remarkable that in this case, as in Porter's, inflammation seems to have taken place in the artery in consequence of the handling to which it was subjected, and that the pulsation in the sac consequently diminished.

The difficulties of the operation arise from the depth of the vessel, from its proximity to the heart, and from the neighbourhood of large veins, which may become turgid, and a wound of which not only obscures the incision with venous blood, but is accompanied by the danger of entrance of air. The artery lies behind the sterno-clavicular articulation and the upper part of the sternum, and bifurcates at the level of the upper border of the clavicle. In front of it are the sterno-hyoid and sterno-thyroid muscles, and it is crossed near its upper part by the right inferior thyroid vein, and lower down by the left innominate. To the right side is the right innominate vein. The pneumogastric nerve is behind and to the outer side, not being in close relation with the artery. Behind the vessel are, at first the trachea, then the pleura, the trachea being now internal to the artery. The artery may be reached in the dead body by an incision starting from the sterno-clavicular articulation, and carried upwards for about three inches between the two heads of the sterno-mastoid, but this would not be justifiable in the living subject, as it does not give sufficient space. The early steps of the operation should be the same as in ligature of the lower part of the carotid (see p. 172). The sterno-hyoid and sterno-thyroid muscles must be freely divided, and the carotid exposed as low down as possible. This vessel serves as the guide to the innominate, the finger being passed along it till the bifurcation of the main trunk can be felt. The needle is then guided by the finger, and passed round the artery from the outer side. It is evident that the vessel cannot be clearly exposed in this mode of operating, and the needle is therefore passed somewhat in the dark. To overcome this difficulty, Cooper removed the inner end of the clavicle and part of the sternum in both his cases, and in Jacobson's case also it was found necessary to remove the inner part of the clavicle.

Even when the difficulties of exposing the artery have been overcome, its coats may be found so diseased, or its calibre so increased, that it may be undesirable or impossible to pass a ligature round it.

W. G. Spencer, as the result of experiments on monkeys, recommends a median vertical incision ; the sterno-mastoid, sterno-hyoid, and sterno-thyroid are retracted without being divided. This suggestion has been put into practice by Coppinger and Twynam.

The results of the ligature of the innominate are in the highest degree

discouraging ; for of all the cases in which it has been done, only three have recovered from the operation.

Of the cases recorded in the table nine died from secondary hæmorrhage ; two from inflammation of the lungs or pleura ; one from pericarditis ; one from diseased kidney ; one from phlebitis and suppuration ; three from cerebral symptoms, and two from causes that are not mentioned.

Of the three cases which recovered from the operation the most remarkable was that in which Smyth of New Orleans was the operator, but it affords no real evidence as to the possibility of safely ligaturing the innominate. For in this case the carotid was also tied so as to stop the regurgitant flow of blood ; yet, notwithstanding this precaution, on the fourteenth day hæmorrhage to syncope occurred. This hæmorrhage recurred at intervals for a period of thirty-seven days, and was temporarily arrested by filling the wound with shot, till, on the fifty-first day after the operation, a "terrific" hæmorrhage took place, stopped by syncope. As this bleeding came from the distal side and from the subclavian artery, the vertebral was tied, with perfect success—no bleeding recurring. This fact is of the utmost surgical value ; it shows that the secondary hæmorrhage, which may be looked upon almost as the necessary sequence of the ligature of the innominate artery, may be arrested and the patient's life saved by the ligature of the principal arterial branch that communicates with and that carries regurgitant blood into the distal end of the artery which was originally ligatured. I am indebted to Smyth for the further history of this case. After ten years of good health, in which the patient was able to follow his employment as a ship's steward, the pulsation returned and the aneurism reached a size larger than before. Thinking it might be fed by the internal mammary, Smyth ligatured that vessel, but without result. About six months later an abscess formed over the sac, and the aneurism became diffused into it, and as a last effort to save the patient's life, the sac was laid open. The hæmorrhage was profuse, and the openings of the vessels into the sac could not be seen, so that the operator had to content himself with plugging the wound. The patient died a few days after. The *post-mortem* examination showed that the circulation had been carried on chiefly by means of the nortie intercostals and branches of the axillary artery. In Banks's case, recorded by Jacobson, the patient recovered from the operation, and was able to leave the Liverpool Royal Infirmary on the twentieth day with the wound soundly healed. Recurrence of pulsation and rapid increase of the aneurism soon occurred, and on the sixty-seventh day after the ligature of the innominate the first part of the subclavian was tied with a double catgut ligature. A few days after the operation the patient became much exhausted by an attack of broncho-pneumonia. Death occurred after repeated attacks of secondary hæmorrhage on the thirty-seventh day.

Coppinger's remarkably successful case is quite unique, in that the patient recovered from the operation without any complication, the aneurism being cured. The operation was performed on January 9th, 1893, in the Mater Misericordiæ Hospital, Dublin, and I am indebted to Coppinger for the fact that in July, 1894, the patient was in perfect health, and the right arm normal in size and strength. At this time the radial artery could be felt distended with blood, but without pulsation.

**Ligature of the First Part of the Right Subclavian** has been performed for aneurisms situated behind or beyond the scalenus. When we consider the anatomical relations of that portion of the subclavian which intervenes between

the innominate artery and the tracheal edge of the scalenus anticus, we are at once struck with the great difficulties of this undertaking; and when we reflect on the position in which the ligature will be placed between the onward current of blood in the innominate on the one side, and the regurgitant stream conveyed by the vertebral, the thyroid axis, the internal mammary and superior intercostal, into the subclavian, immediately beyond the seat of deligation on the other side, we can scarcely anticipate any but the most disastrous results.

With reference to the mere difficulties of the operation, Fergusson justly characterizes it as the most serious in Surgery; the proximity of the common carotid artery on one side, the internal jugular vein on the other, the innominate vein below, the vagus and numerous small venous trunks in front, the recurrent laryngeal nerve and pleura behind, constitute relations of sufficient importance to justify Fergusson's opinion. But supposing these difficulties overcome, and the ligature applied, this must be situated, as has just been stated, in such a position, with a strong current of blood flowing upon each side of it, as to render the formation of an internal coagulum impossible, and thus up to the present time secondary hæmorrhage has invariably occurred, when the ligature separated. In Banks's case (see Table, p. 192) a double catgut ligature was applied without dividing the coats, but hæmorrhage occurred on the 31st day and the patient died on the 37th. Besides the danger of secondary hæmorrhage from these causes, there would be the additional risk of the coats of the artery being diseased, and thus being rendered insusceptible of healthy repair; ulceration and sloughing would take place along the track of the ligature, making a recurrence of hæmorrhage probable. Thus, in Colles's case it was seen, on exposing the subclavian artery, that the aneurism had extended in such a way towards the carotid that it was doubtful whether any part of the affected vessel continued sound. On exposing fully, it was found that only a space of the vessel three lines in length remained free between the sac and the bifurcation of the innominate, and it was in this narrow space that the ligature was applied.

The first part of the right subclavian has been ligatured in fifteen cases, all of which proved fatal: thirteen from hæmorrhage, one from inflammation of the pericardium and pleura, and one from pyæmia. The cases are as follow:—

NAME.	SEX.	AGE.	DATE OF DEATH.	CAUSE OF DEATH.
COLLES.	m.	39	4th day.	Hæmorrhage.
MOTT.	f.	21	18th day.	Hæmorrhage.
HAYDEN.	f.	57	12th day.	Hæmorrhage.
O'REILLY.	m.	39	13th day.	Hæmorrhage.
PARTRIDGE.	m.	38	4th day.	Pericarditis and pleurisy.
LISTON.*	m.	...	13th day.	Hæmorrhage.
LISTON.†	m.	...	36th day.	Hæmorrhage.
CUVILLIER.‡	m.	...	10th day.	Hæmorrhage.
RODGERS.	m.	42	14th day.	Hæmorrhage.
AUVERT.§	...	...	11th day.	Hæmorrhage.
AUVERT.§	...	...	22nd day.	Hæmorrhage.
ARENDT.	m.	34	5th day.	Pyæmia.
RAYE.	m.	21	24 hours.	Hæmorrhage.
HOBART ‡	f.	...	16th day.	Hæmorrhage from the carotid.
BANKS.	m.	50	37th day.	Hæmorrhage.

\* In this case the carotid was also tied, but the hæmorrhage came from the subclavian (Fig. 484).  
† Fig. 483. ‡ Carotid also tied. § Referred to by J. H. Power.

Thus it will be seen that, while the operation is bad in principle, it is most unfortunate in practice. This appalling Table needs no comment. It is, to my mind, conclusive as to the merits of the operation, the patient having, in every case but two, been carried off by secondary hæmorrhage in consequence

Fig. 483.—Ligature of the Subclavian in the First Part of its Course, by Liston.

of the close proximity of numerous collateral branches (Fig. 483); and in the two exceptional cases the operation proved fatal, in one instance from pericarditis and pleurisy, and in the other from pyæmia, before the period at which secondary hæmorrhage might have been expected. Liston, in one case, ligatured the root of the common carotid, as well as that of the subclavian, hoping in this way to diminish the risk of secondary hæmorrhage, by arresting the current

Fig. 484.—Ligature of the Subclavian and Carotid for Subclavian Aneurism, by Liston.

of blood, which by sweeping into the carotid past the mouth of the subclavian, would necessarily wash away any coagulum that might be formed in this artery. But hæmorrhage took place as usual, and from that portion of the artery which lay on the distal side of the ligature, the blood having been carried into this end of the vessel through the connexion existing between the vessels arising from it at this point, and those on the opposite side of the head and neck, as illustrated by the annexed cut (Fig. 484), taken from the preparation of the case in the University College museum. Indeed, this is the great danger to be apprehended after ligature of the first part of the subclavian artery, depending as it does on the anatomical relations and connexions of the vessel, which no skill on the part of the operator can in any way lessen, and which, in my opinion, ought certainly to cause the operation to be banished from surgical practice, unless further experience with absorbable ligatures shows that they can be applied so as to occlude the artery without risk of ulceration or division of its coats.

The method of operating that has most commonly been adopted is the same as that already described for ligature of the root of the carotid. When the vessels are exposed, the jugular vein is drawn outwards with a copper spatula, and the subclavian is thus brought into view. The needle is passed from below upwards.

**Ligature of the First Part of the Left Subclavian** is scarcely

practicable, on account of the depth at which the artery is situated. It has, however, been performed in one case by J. R. Rodgers of New York ; and it was attempted once by Astley Cooper, who failed to secure the vessel, and is said to have wounded the thoracic duct. In another case McGill exposed the artery, and temporarily compressed it with a pair of forceps. The pleura was wounded in the operation, and the patient died on the sixth day, of pleurisy.

**Ligature of the Third Part of the Subclavian** is rarely practicable in cases of subclavian aneurism, as this part of the vessel is more or less completely covered by the sac. Poland has, however, collected twenty-one cases in which this operation has been performed for subclavian or subclavio-axillary aneurism. Of these nine recovered. The sac was punctured in two cases—by Liston and Travers. The majority of the deaths were from hæmorrhage. Warren relates a remarkable case occurring in a lady aged thirty, who was afflicted with an aneurism just above the clavicle. The patient was excessively deformed from club-foot and curvature of the spine, so that the two first ribs rose above the clavicle, passing obliquely across the neck and carrying the artery upwards and backwards, so that it lay parallel to, and about an inch from, the external border of the trapezius. This peculiarity of position enabled Warren to tie the artery on the cardiac side of the tumour, and the case had a successful issue.

The results of the treatment of subclavian aneurism by the application of a ligature to the innominate or to the first part of the subclavian have been so disastrous that a repetition of these attempts can hardly be recommended.

What then are we to do? Are we to leave patients labouring under aneurism of the subclavian artery to inevitable death, without making an effort to save them? Or does surgery offer other modes of treatment besides those just mentioned, by which we may hope to arrive at more successful results?

We have already seen that in all cases constitutional treatment and complete rest must first be tried ; that these may be combined with direct pressure over the aneurism or distal compression of the artery whenever possible ; and lastly, that galvano-puncture, acupuncture, and perhaps manipulation are worthy of further trial.

Two other modes of treatment present themselves :—

1. Distal Ligature of the third part of the Subclavian.
2. Amputation at the Shoulder-joint, and Distal Ligature of the artery.

1. **Distal Ligature of the Third Part of the Subclavian Artery** may, perhaps, hold out some prospect of success in cases of aneurism situated behind or internal to the scalenus. In an aneurismal sac springing from the artery in this situation, the principal current of blood would, in all probability, be that which is destined for the supply of the upper extremity. Some of the branches arising from the artery before it has passed beyond the scalenus anticus would, doubtless, be more or less compressed, and thus obliterated by the tumour ; or they might be obstructed by an extension of the laminated fibrin over their orifices. If, therefore, the supply to the upper extremity could be cut off, there might be a possibility of those changes taking place within the sac which are necessary for the obliteration of its cavity. The principal obstacles to this result would be the transverse cervical and supra-scapular arteries ; which, being the vessels that chiefly carry on the circulation in the upper extremity after the ligature of the subclavian, would necessarily,

if not occluded, undergo dilatation, and thus continue to draw too large a current of blood through the sac for stratification of its contents to take place; and, if they were occluded, there would be danger of gangrene of the arm.

Dupuytren ligatured the axillary artery under the pectoral muscles for a case of subclavian aneurism, two arterial branches being divided in the incisions through the fat and areolar tissue; and the patient died on the ninth day. This operation could not be expected to succeed; for between the ligature and the sac are the alar, acromial, and thoracic branches of the axillary artery, which would continue to be fed by a current sent through the aneurism. Laugier performed the distal operation in a supposed case of subclavian aneurism, which afterwards proved to be one of the innominate artery. In addition to Dupuytren's case, the operation has been done by Pêtrequin, Schuh, and Canton, in all instances without benefit.

2. The above-mentioned difficulties are met by a procedure, originally suggested, I believe, by Fergusson. It is **Amputation of the Arm at the Shoulder-joint**, followed by **Distal Ligature of the Artery**—a desperate undertaking, truly, but for a desperate disease which under ordinary surgical treatment is almost incurable.

The artery might be ligatured before the amputation. "It is known," says Fergusson, "that amputation at the shoulder-joint is generally a very successful operation; so far as this wound is concerned, then, there might be little to apprehend, but the effect on the tumour is not so easily foretold. Ligature of the axillary artery on the face of the stump might here be reckoned like Brasdor's operation; yet there is a vast difference, for in the latter case the same amount of blood which previously passed towards the upper extremity would still find its way down, and probably part of it would run through the sac; whereas were the member removed, as the same quantity would no longer be required in this direction, the tumour might possibly be much more under the control of pressure. The value of such a suggestion remains yet to be tested, however, and it would be futile to reason upon it at present. It might be a judicious venture first to tie the axillary under the clavicle; and then, if it were found that the aneurism still increased, amputation might be performed, either immediately before or after the separation of the ligature."

In the treatment of an aneurism of the first part of the subclavian artery, in which the simpler methods, especially distal pressure, had failed, I should recommend ligature of the artery in the third part of its course, and should this fail, amputation at the shoulder-joint. Should the aneurism occupy the third part of the artery, direct pressure on the sac is probably the best of the simpler methods of treatment. If these fail I should recommend amputation at the shoulder and ligature of the artery as near the sac as possible. It is true that the ligature would be below the branches that are given off under the pectoral muscles; but, as the arm would be removed, they could not undergo any dilatation for the supply of the collateral circulation of the upper extremity.

The first case in which this operation was performed, was by Spence in 1864. The patient lived for four years; and, although the aneurism was not cured, the result afforded good promise of success for the future. For the first ten days after the operation, the pulsation was scarcely to be felt; and when the patient left the hospital the tumour had diminished to one-third of its former size. The artery was tied in two places—where it was cut, and also just beyond the tumour. Before the patient's death—which probably

arose from internal aneurism—the tumour had increased somewhat towards the chest. Since this Holden and Heath have performed the operation, but without success. In both cases, however, the aneurism was traumatic in its origin, and had attained a large size before amputation was practised. Hence the chances of consolidation and cure were materially lessened.

**Ligature of the Vertebral Artery.**—This difficult operation was first performed on the living body by Smyth of New Orleans for the arrest of regurgitant hæmorrhage after ligature of the innominate for subclavian aneurism (p. 194). I will give the details of the operation in his own words :—"The head of the patient being thrown back and slightly turned to the left, an incision two inches in length was made along the posterior border of the sterno-mastoid muscle, commencing at the point where the external jugular vein crosses this muscle and terminating a little above the clavicle ; the edge of the muscle being exposed and drawn to the inner side, the prominent anterior tubercle of the transverse process of the sixth cervical vertebra was readily felt and taken for a guide. Immediately before this and in a vertical line with it lies the artery. A layer of fascia was now divided ; some loose cellular tissue with lymphatics and the ascending cervical artery were pulled to the inner side ; and a separation was made between the scalenus anticus and longus colli muscles just below their insertion into the tubercle, when the artery and vein became visible ; the latter was drawn to the outer side (this is important), and the needle passed around the former from without inwards."

In 1881, Alexander of Liverpool suggested ligature of the vertebral as a means of curing or relieving epilepsy, and performed the operation in several cases with apparent benefit, but the improvement was merely temporary and he abandoned the treatment.

#### ANEURISM OF THE AXILLARY ARTERY.

This artery, though less commonly the seat of aneurism than other large vessels, such as those of the ham, the groin, and the neck, yet is not unfrequently diseased. This is due chiefly to its proximity to the shoulder-joint which causes it to be subjected to very extensive, and often forcible movements. Amongst the most frequent causes of axillary aneurism, may be mentioned falls upon the shoulder or upon the outstretched hands, and in many cases the efforts to reduce old standing dislocations, instances of which are recorded by Pelletan, Flaubert, Warren, and Gibson, the head of the bone in these cases having probably contracted adhesions to the artery. Axillary, like subclavian aneurism, occurs more commonly on the right than on the left side ; of 37 cases, only 3 occurred in women. Furner of Brighton has recorded a case in which both axillary arteries were affected, an interval of about fifteen months intervening between the formation of the two aneurisms ; the subclavian was ligatured on both sides successfully.

**Symptoms.**—In axillary aneurism there are three sets of symptoms : the existence of a tumour in the axilla, the pain that it occasions, and the affections to which it gives rise in the limb.

The tumour, which is at first soft and compressible, has usually a whizzing bruit ; and its pulsations, which are expansile, may be arrested by pressure upon the subclavian artery, where it passes over the first rib. It usually increases with great rapidity, owing to the little resistance opposed by the loose areolar tissue in this situation, and most commonly extends downwards and forwards, causing

the hollow of the axilla to disappear, but it is prevented from extending much beyond the space by the dense fascia stretching from one fold of the axilla to the other. In some rare instances, however, when the aneurism springs from the part of the artery above the pectoralis minor, the tumour takes a direction upwards into the areolar interval above that muscle, or even underneath the clavicle into the interval between it, the acromion and the trapezius. It is fortunately rare for an aneurism to take such a course, as it then presents serious difficulty in the compression or ligature of the subclavian; and there is more than one instance on record, in which the sac has been punctured in the attempt to pass the needle round this vessel. When the aneurism is seated high up, it not unfrequently happens that the clavicle is pushed upwards by the tumour—a complication of considerable moment in reference to the operation, the difficulties of which are greatly increased by it. The *pressure* of the tumour upon neighbouring parts may give rise to serious consequences: thus it may produce a carious state of the first and second ribs, and the compression of the brachial plexus will occasion pain and numbness in the upper extremity. The *affections* of the limb occasioned by the aneurism are diminution or extinction of the radial pulse, œdema, coldness and loss of muscular power. In some cases the brachial artery beyond the tumour would appear to be obstructed, no pulsation being perceptible in it. Compression of the axillary vein may occasion œdema of the hand and arm, with some diminution in the temperature of the limb; and these symptoms, if the tumour attain a very large size, may amount even to indications of impending gangrene.

**Diagnosis.**—The diagnosis of axillary aneurism is usually readily made, there being but two diseases with which it can well be confounded, viz., chronic enlargement and suppuration in the glands of the axilla, and pulsating tumour of the bones in this region. From *glandular* or *other abscess*, the diagnosis is generally easy; but I have seen cases in which, pulsation being communicated to their contents by the subjacent artery, it was somewhat difficult to distinguish the nature of the disease. Here, however, the history of the case and its speedy progress to pointing will indicate its true nature. From *soft pulsating sarcomata of the head of humerus*, the diagnosis is not always so easy; and there are at least two instances on record in which the subclavian artery has been ligatured for disease of this kind on the supposition of its being an aneurism. In these cases, however, it has generally been observed that the tumour first made its appearance on the fore part of the shoulder, and not in the usual situation of axillary aneurism; that it was from the first firm, smooth, elastic, but nearly incompressible; and that, although it presented distinct pulsation, there was no true bellows-sound, but rather a thrilling bruit perceptible in it. The most important diagnostic mark, perhaps, is that these tumours form a prominence in situations in which aneurisms of the axillary artery would not at first show themselves, as at the upper, outer, or anterior part of the shoulder. In more advanced stages, when the bone has become thin and expanded by the outward pressure of the tumour, there is often a characteristic egg-shell crackling on pressure.

**Treatment.**—I am not acquainted with any instance in which an aneurism of the axillary artery, not arising from wound or injury, has undergone spontaneous cure, or has been consolidated by constitutional treatment. Compression or ligature of the subclavian in the third part of its course is the only means of cure.

Axillary aneurisms are favourably situated for the employment of *digitalis*

*compression.* By this means the subclavian can easily be commanded as it passes over the first rib. And the success of this treatment is likely to be great : first, because, the sac being usually large, a considerable quantity of the contained blood is well out of the current of the circulation, readily stagnates and may thus easily coagulate ; and secondly, because the current of blood through the sac is proportionately small, and thus, if coagulation once begin it may easily be completely arrested. Digital compression, therefore, in my opinion, should always be had recourse to in the first instance. By this means, aided by rest and constitutional treatment, the progress of the tumour may be stayed, and possibly a consolidation of its contents and cure be effected. This occurred in a patient seventy-one years of age, in whom an axillary aneurism as large as a shaddock and of an actively progressing character was cured by intermittent digital pressure continued at intervals for between two and three weeks, during which time compression was kept up in all about twenty-three hours, the consolidation commencing on the third day of treatment after seven hours of pressure had been tried. Holmes mentions eight cases in which digital compression was tried. Three of these, under the care of Ciniselli, Dutoit, and another Surgeon whose name is not mentioned, were of traumatic origin, and of these two were cured. The remaining five were idiopathic. Three of these, under Cooper Forster, Peatson, and Rizzoli, were cured. Two, under Turet and Vanzetti, failed. In Cooper Forster's case the compression was applied twice under chloroform : on one occasion for three and a quarter hours and on the other for eight hours. In Peatson's case the pressure was applied at intervals for a period of nearly three months. In Rizzoli's case the treatment lasted even longer, the cure not being complete for nearly six months. In this case the artery was so dilated and diseased that ligature was impossible. In Dutoit's case the compression was applied for six hours a day for six days. Lund has also recorded a case cured by digital compression in two periods, the first of ten and the second of seven and a half hours. In another case under the care of S. Jones, compression was combined with the application of Esmarch's bandage to the arm, but without success.

Compression by instruments on the cardiac side can seldom be made applicable to aneurisms in this situation ; inasmuch as the pressure that is brought to bear upon the subclavian must necessarily at the same time influence the greater part of the brachial plexus of nerves to such an extent as to be unendurable by the patient. Yet it is not impracticable, and means might be devised to overcome this difficulty.

Ligature of the artery is, however, still the Surgeon's chief resource in the treatment of these cases. The part of the vessel universally selected for the application of the ligature is that which lies on the first rib beyond the *scalenus anticus* muscle ; this part presents the advantages of being sufficiently removed from the seat of disease to ensure the probability of the coats being in a sound state, of being by far the most accessible, and, when deligated, of allowing the collateral circulation by which the vitality of the arm is to be maintained to remain uninjured.

**Ligature of the Third Part of the Subclavian.**—In order to apply a ligature to that portion of the subclavian artery which intervenes between the outer edge of the *scalenus anticus* and the outer border of the first rib, the patient should be placed in the recumbent position, the arm de-

pressed as much as possible, and the head turned somewhat to the opposite side. The situation of the external jugular vein should then be ascertained if possible before commencing the incision. It may lie at any point between the posterior border of the sterno-mastoid and the edge of the trapezius; most commonly it is close to the former muscle, and occasionally it is wanting. The operation is commenced by drawing the integuments of the lower part of the neck downwards over the clavicle and making an incision about four inches in length upon the bone, dividing the skin, superficial fascia, platysma, and the supraclavicular branches of the cervical plexus. When the tension is

Fig. 485.—Ligature of the Subclavian in the Third Part of its Course.

taken off the part, this incision will be found to traverse the base of the posterior triangle of the neck. The chief object of drawing the skin downwards is to avoid any risk of wounding the external jugular vein, for as this vessel perforates the deep cervical fascia about one finger's breadth above the clavicle, it cannot be drawn downwards with the integuments. Sometimes the cephalic vein crosses the clavicle to join the external jugular, and it would then necessarily be divided in the first incision. The next step in the operation is to find the external jugular vein. In order to do this the deep cervical fascia must be carefully dissected through close to the clavicle; immediately beneath the fascia a quantity of loose areolar tissue is exposed, in which the lower end of the vein will commonly be found. As soon as the deep cervical fascia is divided great caution must be used,

the areolar tissue being picked up in small pieces with the forceps and scratched through with the point of the scalpel or torn with a blunt probe or steel director. When the external jugular vein comes into view it must be treated according to its position : if at either end of the wound, it may be drawn aside with a blunt hook ; if in the middle, a double ligature must be passed and the vein tied in two places and divided between them. Occasionally the transverse cervical and suprascapular veins form a plexus with the external jugular immediately above the clavicle, and the difficulty of exposing the artery is then greatly increased. The transverse cervical artery lies normally above the wound, and the suprascapular is concealed behind the clavicle, but in exceptional cases they may be found in the space exposed in the operation. They must then be drawn out of the way with blunt hooks. By carefully teasing through the areolar tissue, the external edge of the scalenus anticus is reached ; this is the "directing line" down which the finger is run until the tubercle of the first rib is felt. This is the guide to the artery, which will be found immediately above and a little behind it, covered, however, and bound down by a dense fascia. Immediately above the artery, and in close contact with it, is the lowest cord of the brachial plexus, that

Fig. 486.—Diagram of Right Subclavian Artery in Third Part of its Course, crossed by transversalis colli artery and vein. *a*. Subclavian artery. *v*. External jugular receiving transversalis colli veins. *n*. Brachial plexus of nerves. *m*. Omohyoid muscle.

Fig. 487.—Diagram of the Relations of the Third part of the Subclavian Artery : *t*. trapezius ; *o.h.* omohyoid ; *s.a.* scalenus anticus ; *s.m.* sternomastoid ; *v*. external jugular vein ; *n*. brachial plexus ; *a*. artery.

formed by the last cervical and first dorsal nerves ; beneath the artery is the first rib, upon which it can be felt rolling under the finger when firm pressure is made. At the same time pulsation will be felt, but this must not be taken as proof that the structure beneath the finger is the vessel, for the lowest cord of the brachial plexus lies so close to the subclavian artery that it receives a communicated impulse from it. On firm pressure the nerve still retains its round form, while the artery flattens out, and its surface becomes slightly concave. The thick fascia covering the artery having been carefully opened with the edge of the knife, the needle is passed from the nerve, as low down as possible, so as to avoid any risk of injuring the pleura by slipping over the inner border of the first rib. The subclavian vein is so far below the clavicle that there is no possibility of wounding it. In a considerable proportion of cases the posterior scapular artery will be found springing from the main trunk in this part of its course. In 296 arteries examined by Quain, it arose from the third part as a separate branch in 101, or as nearly as possible one in three cases. If this condition is met with, the ligature must be applied as far as possible to the proximal side of the branch. If necessity requires the ligature to be applied close to the branch, it is perhaps

safer to tie this also, as the anastomosis of the vessels in this region is so abundant that the risk of gangrene from the obliteration of a single branch would be very small.

The operation just described is that commonly adopted. In order that it should be easily carried out, it is in the first place necessary that the shoulder should be depressed as far as possible, so as to bring the clavicle down. This is a matter of much importance ; for, if the clavicle be thrust upwards by the pressure of a large aneurism, or if it lie high in consequence of emphysema of the lungs, the Surgeon will have to find the artery at the bottom of a deep wound, instead of on a comparatively plane surface. If, therefore, the clavicle cannot be thoroughly depressed, more room must be provided in the superficial parts of the wound. This is done by making a vertical incision upwards either along the border of the sterno-mastoid or from the middle of the wound for about two inches. As the artery is in these cases approached rather from above than from the front, the structures met with differ somewhat from those already described. The posterior belly of the omo-hyoid is always exposed, and forms an important rallying point in the operation, and the transverse cervical artery and vein will most commonly come into view. The danger of including the lowest cord of the brachial plexus is greater the more the artery is approached from above. The vertical incision should always be made in fat subjects.

In some cases the clavicle may lie so high that the artery cannot be exposed even with the help of the vertical incision. A case occurred to Astley Cooper, in which the attempt to ligature the subclavian artery for a large aneurism of the axilla had to be abandoned, in consequence of the clavicle being thrust up to too great a height to allow him to reach the vessel. The extent of the difficulty occasioned by this elevation of the clavicle must necessarily depend in a great measure upon the height at which the subclavian artery happens in any particular case to be situated in the neck. It is not uncommon to find it pulsating so high in the neck that no amount of elevation of the clavicle by a subjacent axillary aneurism could raise that bone above the level of the vessel. In the majority of cases, however (in seventeen out of twenty-five, as shown by Quain,) it is either below the level of the bone, or but slightly raised above it ; so that, if the clavicle were thrust upwards and forwards, the vessel would be buried in a deep pit behind it. Dupuytren was of opinion that the artery coursed high in persons who were thin, with slender long necks ; whereas, in thick, short-necked persons, with muscular shoulders, it was deeply seated. I have often verified the truth of this observation, both in dissection and in examining the pulsations of the vessel during life.

In order to obviate the difficulty that has occasionally been experienced in reaching the artery when thus buried behind an elevated clavicle, it was proposed by Hargrave to saw through the bone. The most serious objection that can be raised against this practice, is the fact that the clavicle is sometimes a part of the wall of the aneurism : but, supposing the Surgeon could satisfy himself that this was not the case, I cannot see any objection to this procedure, provided any insurmountable difficulty presented itself in passing the ligature round the vessel without it.

The artery occasionally takes a remarkably high course in the neck, and in some of these instances instead of passing over the first dorsal rib, it is sup-

ported on a supernumerary cervical rib, the anatomical relations being thus seriously disturbed. And again, if this supernumerary cervical rib be unusually short, the vessel may be found to lie between it and the first dorsal. Another abnormality of great rarity is the passage of the subclavian vein behind the scalenus anticus with the artery. This would add greatly to the difficulty of the operation.

The *Collateral Circulation* after ligature of the third part of the subclavian is carried on by the anastomoses of the posterior scapular and suprascapular branches of the subclavian with the subscapular and acromio-thoracic branches of the axillary, and by the anastomoses of the aortic intercostals, superior intercostal, and internal mammary with the thoracic branches of the axillary.

**Accidents during Ligature of the Third Part of the Subclavian.—**

*Wound of the External Jugular Vein* is a most serious complication, as entrance of air is very likely to take place, and may cause immediate death. This accident is avoided by careful dissection, and if the vein is so situated as to be exposed to the risk of injury, it must be divided between a couple of ligatures.

*Profuse venous hæmorrhage* from wound of some of the numerous veins in the neighbourhood has more than once prevented the completion of the operation. Should this accident happen the wound must be plugged and the operation attempted again at some later period.

*Wound of the Sac* is a somewhat rare accident. In some cases, when the sac passes upwards beneath the clavicle into the posterior triangle of the neck, the Surgeon incurs the risk of puncturing it from its close proximity to the artery. This accident happened to Cusack while ligaturing the subclavian in the third part of its course, for a diffused aneurism of the axillary artery. An alarming gush of blood took place, which was arrested by plugging the wound; but the hæmorrhage recurred on the tenth day, and the patient died. In a case related by Travers, in which the sac was punctured as the needle was being passed round the artery, the blood did not flow *per saltum*, but in a continuous stream. "The hæmorrhage," Travers says, "was more terrific and uncontrollable than I have ever witnessed," and was not commanded by tightening the ligature. It was so great that it was doubtful whether the patient would leave the theatre alive, and it was arrested only by plugging the wound with sponge-tents. The patient died of inflammation of the pleura. On examination, it was found that a pouch-like enlargement of the aneurism overlying the artery had been punctured.

*Inclusion of the lowest cord of the brachial plexus* in the noose of the ligature is a more common accident; indeed the mistake has more than once been committed of tying this nerve-trunk instead of the vessel. Thus, Liston, in the first successful case of ligature of the subclavian in this country, passed the thread round the lower cord; but immediately perceiving his error, turned it to account by drawing aside the included nerve, and thus more readily exposing the artery. Dupuytren, in a case of aneurism of some years' duration, succeeded, after an operation that lasted one hour and forty-eight minutes, and which he describes as the most tedious and difficult he ever attempted, in passing a ligature round the vessel, as he believed. After the death of the patient from hæmorrhage on the ninth day, the artery was found to have been perforated by the needle, and one half of the vessel and the lower cord of the brachial plexus included in the noose. In a case related by Porter,

it is stated that the artery communicated such distinct pulsation to the nerve-trunk, that there was no means of ascertaining whether it was the vessel or not, except by passing the needle under it.

*Puncture of the pleura* in passing the needle is not usually recognized as one of the dangers of ligature of the third part of the artery. It may, however, take place, especially if the needle is passed close to the scalenus anticus and from above, as must often be the case when the clavicle is much raised.

**Ligature behind the Scalenus anticus.**—If the sac encroach upon the neck, rising above the clavicle, or the artery be not sound in the third part of its course, it may be necessary to ligature it behind the scalenus anticus, dividing the outer half or two-thirds of the muscle. This operation should not be considered as distinct from ligature of the vessel in the third part of its course, but rather as an extension of that proceeding, if it be found, for the reasons just mentioned, unadvisable to tie the artery on the first rib; in this way it was practised by Dupuytren and Liston. In its first steps, as far as the exposure of the scalenus anticus, it is the same as that for the deligation of the vessel in the third part of its course. When this muscle has been exposed, it may be partially or completely divided by picking up the fibres with forceps and dividing them with a scalpel held horizontally. During this part of the operation, some danger may be incurred by the phrenic nerve, and the transverse cervical and suprascapular arteries; but if ordinary care be taken, this will not be very great. The phrenic nerve lies altogether to the tracheal side of the incision, if that be not carried beyond one-half the breadth of the muscle; and should it appear to be in the way, it may readily be pushed inwards towards the mesial line, being only loosely invested by areolar tissue. I have, however, seen one instance in which the right subclavian artery was ligatured for a spontaneous aneurism of the axilla, and the patient died on the eighth day, of pneumonia; on examination after death, the edge of the scalenus was found cut, and the phrenic nerve divided. Had the injury to the nerve in this case anything to do with the pneumonia? I do not think it improbable; as division of one phrenic nerve, by paralysing to a certain extent the diaphragm, and so far interfering with the respiratory movements, must necessarily have a tendency to induce congestion of the lung, which would predispose to inflammation of that organ. I have likewise heard of one case in which incessant hiccough followed this operation, and after death the phrenic nerve was found reddened and inflamed, having probably been interfered with in some way during the exposure of the vessel. The transverse cervical and suprascapular arteries may be avoided by keeping the incision in the muscle between and parallel to these vessels.

Another important point in reference to the ligature of the vessel in this part of its course is, that in five cases out of six on the right side and in one-half on the left, the superior intercostal arises from the subclavian artery between the scaleni. When this is the case, there would probably be but a slender chance of the occlusion of the artery by ligature in this situation.

Godlee has recently tied the second part of the left subclavian successfully for axillary aneurism. The third part was so dilated and soft that it was not thought safe to apply a ligature to it. The scalenus anticus was therefore completely divided, and a ligature composed of four strands of the finest chromic catgut applied to the artery without division of the coats. Neither the phrenic nerve nor the thoracic duct came into view.

One principal danger in ligaturing the subclavian artery at any point above the first rib, certainly arises from interference with the fascia which lies between it and the scaleni, separating it from the pleura. This fascia is continuous with the areolar tissue of the anterior mediastinum, being indeed the deep portion of the ascending layer of what Astley Cooper described as the "thoracic fascia," which helps to form the superior boundary of the chest, being continuous in the neck with the deep cervical fascia. After the deeper layers of the cervical fascia have been opened, this fine areolar tissue presents itself; and, if septic inflammation follow, it will readily extend by continuity of tissue into the anterior mediastinum, invading ultimately the pleura and pericardium. Hence, whenever it is practicable, the Surgeon should keep the point of the needle close to that part of the artery which lies upon the first rib, as there is less risk here of opening into the deep areolar tissue of the neck.

**Results of Ligature of the Subclavian.**—The general results of ligature of the subclavian in the third part of its course for spontaneous aneurism in the axillary are by no means satisfactory. Thus of 48 cases of aneurism of the axillary artery, not dependent upon any external wound, in which the artery was ligatured above the clavicle, I found 23 cures against 25 deaths. This result was so unfavourable, and so different, indeed, from what I anticipated, that I was led to analyse carefully the causes of death. I found them as follows:—

Inflammation within the chest, &c. . . . .	10 cases.
Suppuration of the sac . . . . .	6 "
Suppurative phlebitis . . . . .	1 "
Hæmorrhage . . . . .	3 "
Gangrene of hand and arm . . . . .	1 "
Gangrene of both arms and legs . . . . .	1 "
Not stated . . . . .	3 "

*Inflammation of the Contents of the Thorax* proved fatal in 10 out of 48 cases, or 1 in 4·8, and is the most frequent cause of death, though not, I believe, the most frequent untoward complication of this operation. It might at first be supposed that the pulmonary complications were due to pyæmia, but, on closer examination, it will be found that this is not the case. Inflammation, when attacking the contents of the thorax after ligature of this artery for axillary aneurism, does not commence in the substance of the lung as in pyæmia, but most commonly affects primarily the pleura and pericardium. It would appear probable, therefore, that it arose from causes that are essentially connected either with this operation or with the aneurism itself. These are referable to three heads:—

1. Septic inflammation of the deep areolar tissue at the root of the neck may extend to the anterior mediastinum, the pleura, and pericardium. This would appear to have been the cause of death in a patient in whom Key tied the subclavian.

2. The sac may, by its pressure inwards, encroach upon and give rise to inflammation of that portion of the pleura which corresponds to its inner aspect. This occurred in a case in which Mayo of Winchester operated, and is more likely to happen if suppuration have taken place in the sac. When

this occurs, adhesion may take place between the sac and the pleura, or even the tissue of the adjacent lung; and the contents of the suppurating sac may be discharged into the pleural cavity or air-tubes, and so coughed up. Of this there are at least two cases on record: one by Bullen, in which the patient recovered; the other by Gross, in which the patient died from the escape of the contents of the sac into the cavity of the pleura.

3. Division of the phrenic nerve would necessarily, by interfering with the respiratory movements, induce a tendency to congestion and inflammation of the lungs; and, although such an accident must be a very rare one in cases of ligature of the subclavian for axillary aneurism, yet it undoubtedly has occurred, as I have myself witnessed in one case.

*Suppuration of the Sac* is the most common, though not the most fatal, accident after ligature of the subclavian for spontaneous axillary aneurism. It was the immediate cause of death in six cases, and occurred in two of the patients that died of inflammation of the chest; it took place in six cases also that recovered: in all, fourteen cases out of forty-five, or nearly one in three,—a much higher proportion than is generally observed in cases of ligature for aneurism.

What occasions this greater frequency of suppuration of the sac in axillary aneurisms than in those in other situations? One important cause appears to be the great laxity of the areolar tissue in the axilla, which allows the tumour, in almost all cases, to increase so rapidly in size as to excite subacute inflammation in the surrounding structures. This may readily become acute and reach the stage of suppuration owing to external violence, to rapid extension of the sac, or to some constitutional affection on the part of the patient. Thus suppuration of the sac is not an uncommon complication of axillary aneurism even when no operation has been performed. When a ligature is applied to the subclavian it is in most cases in close proximity to the sac as the aneurism is commonly seated high in the axilla, and as the loose areolar tissue opened up during the operation in the root of the neck is continuous with that of the axilla, it is evident that should septic suppuration occur in the wound it will readily extend to the already inflamed tissues surrounding the sac. In some cases possibly the sac itself may be damaged during the operation. The statistics collected by Koch show a much greater mortality in those cases in which the subclavian artery has been tied for spontaneous aneurisms extending above the upper border of the pectoralis minor, than in those below that point. Of 17 of the former 13 were fatal; of 22 of the latter only 10 died.

The period at which suppuration of the sac may be expected to occur in cases of axillary aneurism, after the ligature of the subclavian, must necessarily in a great measure be dependent on the state of the sac at the time of the operation. If inflammation have already been set up around it, it may happen a few days after the artery has been tied; otherwise the period at which suppuration may most probably be expected is between the first and second month. The period at which suppuration and rupture of the sac take place does not influence the probable termination of the case to any material extent, as, in the cases that proved fatal, death occurred at various periods between the seventh day and the second month: in Aston Key's case, on the ninth day; in Mayo's, on the twelfth; in Belardini's and Gräfe's, at the end of the first month; in Rigaud's, at the sixth week; in B. Cooper's, in the

second month. The recoveries, likewise, took place at all periods after the ligature of the vessel, between a few days, as in Porter's, and six weeks, as in Halton's, case.

An axillary aneurism that has suppurated may burst either externally, or into the lungs or pleura, or both. It usually bursts externally: the tumour enlarges, with much pain and tension; a part of the skin covering it becomes inflamed; fluctuation can be here felt, and, if an incision be not made, the tumour will give way, discharging dark-coloured pus, mixed with broken-down and disintegrated coagulum, perhaps sooner or later followed by a stream of arterial blood.

Occasionally, but more rarely, the sac, extending inwards, perforates the cavity of the chest and becomes adherent to the pleura, and may give way into its cavity; or, by pressing upon the lungs, may become incorporated with them. Of this remarkable termination two instances are recorded, in one of which recovery took place. The first case is one in which Bullen ligatured the subclavian artery for axillary aneurism. Eighteen days after the operation the tumour began to increase, and symptoms of suppuration developed. On the twenty-sixth day six or eight ounces of bloody pus were expectorated during a paroxysm of coughing, and the tumour suddenly diminished to half its size; it was now punctured, and five ounces of the same kind of matter were let out with great relief. When the patient coughed, air passed into and distended the sac through an aperture between the first and second ribs, through which the contents of the tumour had escaped into the lung. The discharge from the external aperture greatly decreased; the cough lessened; and finally, three months after the operation, the patient was quite well.

Gross tied the subclavian artery for axillary aneurism on the 18th of February. After the performance of the operation the contents of the tumour solidified, and its volume progressively diminished. On the 15th of March the patient suffered from fever, and slight tenderness on the apex of the tumour was perceptible. On the 16th he was suddenly seized with intense pain in the chest, which was most severe at the base of the right lung, and extended up towards the axilla. Respiration throughout the right lung was bronchial, and there was dulness on percussion over the lower ribs; the axillary swelling had suddenly disappeared at the time of the attack. On the 18th the patient experienced a sensation as if a fluid were passing from the pleural cavity into that of the aneurism; and a splashing sound was heard at every inspiration, the noise resembling that produced by shaking water in a closed vessel. On the 20th he died. The aneurism was found to communicate by an aperture, one inch and three-quarters in length and an inch and a half in width, with the pleural cavity; this opening was situated between the first and second ribs, and was obviously the result of ulceration and absorption, caused by the pressure of the tumour. Both ribs were denuded of their periosteum. The right side of the chest contained nearly three quarts of bloody serum, mixed with laminated clots and flakes of lymph.

Besides these cases, a somewhat similar one has been recorded by Neret, of Nancy. A patient was admitted into the hospital, suffering from hæmoptysis, and on examination he was found to have an aneurism of the left subclavian artery as large as a chestnut. He died shortly after admission, and the aneurism was found to communicate with a large cavity in the upper part of the lung.

The cause of death in Gross's case was probably the fact of the sac opening and discharging its contents into the pleural cavity. This does not appear to have occurred in Bullen's, in which a communication was established directly with the lung, the contents of the abscess finding exit through the air-tubes. The process here was analogous to what occasionally occurs in hepatic abscess when this opens through the lungs, adhesion having previously taken place between the opposed surfaces of the pleura.

In Furner's case of aneurism of both axillary arteries, the two subclavians were tied in the third part of their course at an interval of about fifteen months. The patient, a stone mason by trade, made an excellent recovery from the first operation. After the second operation he progressed favourably for twelve weeks, by which time the tumour had diminished so much as to be not more than a third of its original size. Without obvious reason febrile disturbance set in, the tumour enlarged again, and showed signs of suppuration. Furner now made a free incision into it through the pectoral muscle, and let out 18 or 20 ounces of very offensive pus and broken-down coagulum. The patient speedily recovered and the tumour entirely disappeared.

The principal danger, and the most frequent cause of death after the suppuration of the sac, is the supervention of profuse arterial hæmorrhage. This may occur either from the distal extremity of the artery opening into the sac, or from one of the large branches which serve to support the collateral circulation round the shoulder, such as the subscapular or posterior circumflex coming off either immediately above or below the sac, or from the sac itself. When hæmorrhage does not take place after suppuration of the sac, it must be owing to the fortunate circumstance that the main trunk is occluded where it opens into the tumour. It can scarcely be from the occlusion of the principal collateral branches, as there would, in that event, be a difficulty in the preservation of the vitality of the limb. It is easy to understand that, if the sac sprang from the axillary, at a little distance above the orifices of the subscapular and circumflex arteries, all that portion of the main trunk which intervenes between the tumour and these vessels might be occluded, and thus hæmorrhage be prevented on suppuration taking place; whilst the collateral circulation would take place uninterruptedly through these vessels. If this portion of the artery have not been occluded by inflammation, the safety of the patient must depend upon the accident of a coagulum or piece of laminated fibrin being fixed or entangled in the mouth of the sac. This may prevent for a time the escape of arterial blood, which, on the plug being loosened, may again occur, and either at once, or by its recurrence prove fatal.

Another danger may be superadded in these cases to the suppuration of the sac and the supervention of hæmorrhage—namely, the extension of inflammation to the pleura, lung, and pericardium from the sac.

*Secondary hæmorrhage* does not frequently occur in cases of ligature of the subclavian artery in the third part of its course, except as a consequence of suppuration of the sac. I myself have seen but two cases in which death occurred from hæmorrhage taking place from this artery at the part ligatured. One of these happened to Liston, and the preparation is preserved in the Museum of the College of Surgeons (No. 1695). In this case it may be seen that the artery was diseased at the point ligatured, and that the bleeding occurred, as usual, from the distal side of the ligature. Barwell, taking Koch's table of 79 cases, and adding to it 11 collected by himself, finds that

of 32 deaths occurring in the 90 cases, 10 were from hæmorrhage from the site of ligature.

*Gangrene of the Hand and Arm* is but seldom met with as a sequela of this operation. This is doubtless owing to freedom of the anastomosing circulation between the branches of the transverse cervical and suprascapular, and those of the subscapular, circumflex, and acromio-thoracic arteries, as well as between the superior and long thoracic and the branches of the intercostals and internal mammary, by which the vitality of the limb is readily maintained. The principal risk from gangrene would doubtless arise from the subscapular artery being in any way occluded or implicated in the disease, as it is on the anastomoses of this vessel that the limb is mainly dependent for its supply of blood. But, at all events, this danger is small, the only case in which it appears to have brought about a fatal termination being one in which Colles tied the artery; gangrene of the limb came on after much constitutional disturbance, with rapid, weak pulse, thirsts, sweats, restlessness, and delirium. In Blizard's case, there were sloughing of the sac and pericarditis, the gangrene being confined to two fingers; and in Brodie's case, it occurred in both the lower as well as in the upper extremities, and must, therefore, have proceeded from some constitutional cause altogether independent of the mere arrest of circulation through the subclavian.

Failure of the operation to cure the disease if the above accidents are avoided is a very rare occurrence. A case of this kind occurred to Berkeley Hill in University College Hospital. The subclavian was successfully tied for a large axillary aneurism; there was some inflammation about the sac after the operation, which gradually subsided. Some months afterwards the tumour began steadily to increase in size without pulsation, and finally the sac was laid open and the vessel tied from within, and the patient made a good recovery.

On reviewing the causes of death, it may reasonably be hoped that the average of success will be materially increased by the use of ligatures which do not divide the coats, and by the prevention of septic and spreading inflammation in the wound by the employment of antiseptic dressings.

**Treatment of Inflamed Axillary Aneurism threatening Suppuration.**—The case of an axillary aneurism becoming inflamed, and threatening to suppurate *before* the Surgeon has had an opportunity of ligaturing the subclavian artery, is one that is full of important practical considerations, and that admits of little delay; for if the sac rupture, or be opened, fatal hæmorrhage is the inevitable result. It would obviously be impossible, in a case of spontaneous aneurism, with any fair chance of success, to lay open the tumour, turn out the coagula, and ligature the vessel above and below the mouth of the sac; the coats of the artery being not only diseased, but still further softened by inflammation and suppuration, would not be in a condition to hold a ligature. There are two other courses open—viz. ligature of the subclavian, or amputation at the shoulder-joint; and in the selection of one or other of these, the Surgeon must be guided by the progress the disease has made, the condition of the limb as to circulation and temperature, and the solidity or fluidity of the contents of the tumour.

If the tumour be of moderate size and circumscribed, and the arm of a good temperature and not very œdematous, *ligature of the artery* may hold out a reasonable chance of success. It is true that this is but a chance: for the

blood will, immediately after the noose is tied, be carried by the suprascapular and posterior scapular arteries into the subscapular and circumflex, and by them into the axillary at no great distance from the mouth of the sac ; or it may enter directly into the mouth of the latter, if the subscapular or circumflex should chance to take their origin from the dilated portion of the vessel. Hence, the only safeguard against the supervention of hæmorrhage as soon as the sac has burst or been opened, or has discharged its contents, will be the occlusion by thrombosis of that portion of the artery which intervenes between these two collateral branches and its mouth, or the accidental entanglement in the latter of a mass of laminated fibrin. Yet, in the circumstances as to the condition of tumour and limb that have just been mentioned, it would be but right for the Surgeon to give the patient a chance of preserving his arm.

Should, however, hæmorrhage occur on or after the discharge of the contents of the sac, the subclavian having previously been ligatured, if the bleeding be moderate, an attempt should be made to arrest it by plugging the wound, and by the application of a compress and bandage. If it recur, or be so profuse as to threaten the life of the patient, two lines of procedure are open to the Surgeon : either to cut through the pectoral muscles so as to lay the sac open fully, and attempt to include the bleeding orifice between the two ligatures ; or to amputate at the shoulder-joint.

If a Surgeon were to adopt the former of these alternatives in a case of spontaneous aneurism, of which alone we are now speaking, he would, in all probability, find the part in such a condition as would prevent the possibility of his completing the operation he had commenced. After laying open a large sloughing cavity, extending under the pectoral muscles perhaps as high as the clavicle, and clearing out the broken-down coagula contained in it, in what state would he find the artery ? Certainly, the probability would be strongly against its being in such a condition as to bear a ligature, even if it could be included in one. Its coats, in the immediate vicinity of the sac, could not, in accordance with what we know to be almost universally the case in spontaneous aneurisms of large size or old standing, be expected to be in anything like a sound firm state, and would almost certainly give way under pressure of the noose ; or the vessel might have undergone fusiform dilatation, as is common in this situation, before giving rise to the circumscribed aneurism, in which case it would be impossible to surround it by a ligature : or, again, the subscapular or circumflex arteries might arise directly from, and pour their recurrent blood into, the sac or the dilated artery, and, as they would lie in the midst of inflamed and sloughing tissues, no attempt at including them in a ligature could be successfully made. In such circumstances as these, the danger of the patient would be considerably increased by the irritation that would be occasioned by laying open and searching for the bleeding vessel in the sac of an inflamed, suppurating, and sloughing aneurism, and much valuable time would be lost in what must be a fruitless operation : at the close of which it would, in all probability, become necessary to have recourse to amputation, and thus to remove the whole disease at once. I should, therefore, be disposed to have recourse to *disarticulation at the shoulder-joint* at once, in all cases of profuse recurrent hæmorrhage, following sloughing of the sac of an axillary aneurism, which could not be arrested by direct pressure on the bleeding orifice, after the subclavian has been tied.

There is another complication of axillary aneurism that necessitates immediate amputation at the shoulder-joint, whether the subclavian artery have previously been ligatured or not; it is the case of diffuse aneurism of the axilla, with threatened or actual gangrene of the limb.

**Ligature of the Axillary Artery.**—Should ligature of the axillary artery be required at any time, the vessel may be secured in one of two situations—in the space that intervenes between the lower margin of the clavicle, the pectoralis minor, or in the axilla as it lies on the tendon of the latissimus dorsi.

To expose the artery *above the pectoralis minor*, the shoulder must be pushed upwards and allowed to fall backwards as far as possible. An incision is then made, slightly curved with its concavity upwards, commencing immediately above and internal to the tip of the coracoid process, and terminating immediately below the clavicle, and about one inch from the sterno-clavicular articulation. The skin and fat are divided in the first incision, and the pectoralis major exposed. The fibres of the muscle are separated in the inner end of the wound, and the finger introduced into the space beneath guiding a

probe-pointed bistoury, with which the remainder of the muscle is rapidly divided throughout the whole length of the wound. In doing this, several large branches of the acromio-thoracic artery are divided and must be tied at once. The next rallying-point is the upper border of the pectoralis minor. This must be found by tearing through some loose areolar tissue with the forceps and a steel director, so as not to wound the branches of the acromio-thoracic artery and vein. The cephalic vein lies at the outer angle of the wound, and is usually not seen. When the pectoralis minor is found, it must be drawn downwards with a copper spatula. In so doing, the costo-coracoid membrane beneath which the artery lies is brought fully into view. This membrane is seldom sufficiently distinct to be recognized as a definite structure, and it can readily be torn through with a pair of forceps and the steel director. It is perforated by the acromio-thoracic artery and vein, and the external anterior thoracic nerve. These will be seen as the areolar tissue is torn through, and must be drawn inwards with a blunt hook. In the living body the vein next comes into view, and must be drawn inwards, when the artery will be seen to its outer side. The needle must be passed from the vein and as near the

clavicle as possible, well above the origin of the acromio-thoracic. If it is necessary to tie it in close proximity to this branch, it would be safer to apply a ligature to the branch also. In practising the operation on the dead body, the vein often is not seen, and it is customary to find the artery by following the acromio-thoracic to its origin. There is little risk of including a cord of the brachial plexus, as the nerves lie well to the coracoid side, separated by a slight interval from the artery. It is frequently found in the dead body that the ligature has been applied above the outer border of the first rib, the end of the subclavian being actually the vessel tied. This operation is a very difficult one, on account of the depth of the wound and the numerous venous and arterial branches which ramify across the space in which the vessel lies. Ligature of the third part of the subclavian is to be preferred whenever it is practicable.

If it is necessary to tie the axillary, as in the case of a punctured wound, the operation recommended by Guthrie is probably safer and simpler than that just described. It consists in making an incision from the centre of the clavicle directly downwards, in the course of the vessels, to the middle of the anterior fold of the axilla. In this way the skin, superficial fascia, and greater pectoral muscle, must be successively divided. The lesser pectoral will then be exposed; and the artery may be ligatured above or below this, without further division of muscular substance, or if it be thought desirable to tie it under this, the muscle must be cautiously cut through. When this is done, a very distinct and firm fascia will come into view; this must be picked up and carefully opened, when the artery and vein will be seen lying parallel to one another, the artery being to the outer side. The vein having been drawn inwards, the aneurism needle must be carried between it and the artery. The second part of the artery has the three cords of the brachial plexus in close contact with it, the inner lying between it and the vein. At the lower border of the pectoralis minor the inner head of the median crosses the artery. Care must be taken not to include these nerves in the ligature. The great advantage of this operation is, that the wound is open and free, and that, consequently, the artery can be more readily reached in any part of its course. The disadvantage is the great division of muscular substance that it entails. This, however, need not leave any permanent weakness of the limb, as by the use of sutures and by proper position union may readily be effected.

The axillary artery may also be ligatured at any point below the lower border of the pectoralis minor, by making an incision parallel to its course in the axilla. The guiding-line for the vessel in this situation is obtained by dividing the space between the anterior and posterior folds of the axilla into three equal parts, when the artery will be found to lie at the junction of the anterior with the middle third. The arm being held at an obtuse angle with the trunk, so as to make the skin tense, an incision is made, commencing at the thoracic border of the axilla and extending for a distance of about three inches parallel to the course of the artery. The incision must be made so as to divide the skin only. The fascia, being exposed, must be carefully opened, when the axillary vein will come into view, and must be drawn to one side with a blunt hook. The artery will now be seen surrounded by the nerves of the brachial plexus. In front of it or to its inner side is the internal cutaneous. To its inner side between it and the vein is the ulnar; the nerve of Wrisberg is still

further internal, usually beyond the vein. To the outer side is the median, and for a short distance above, the external cutaneous lies on the same side of the vessel before entering the coraco-brachialis. Behind is the musculo-spiral, and as far as the upper border of the *teres major*, the circumflex. The nerves are easily held aside, and the ligature is passed round the artery from the vein. If the ligature be applied near the termination of the axillary artery, as it lies over the tendons of the *latissimus dorsi* and *teres major*, it will not be in immediate contiguity to any large branch. Above this point, it must be applied close to either the subscapular or the circumflex arteries, which would perhaps somewhat add to the danger of secondary hæmorrhage. In a fat axilla there is some risk of missing the artery by drifting too much towards the posterior border of the space. To avoid this, and also to get rid of the inconvenience caused by the situation of the vein covering the artery, Malgaigne recommended that the incision should be made a little nearer the anterior border of the axilla, and the edge of the coraco-brachialis sought as the first rallying-point. When this is found it is drawn slightly forwards, when the median nerve will be seen in contact with it. If this be drawn on one side, the artery at once comes into view. By this method the artery can often be tied without the vein being seen, and it is impossible to miss the vessels by getting too far to the inner side. Ligature of the axillary is very rarely required for aneurism. It has been done as a distal operation for subclavian aneurism, but without success.

The *collateral circulation* after ligature of the axillary above the *pectoralis minor* is the same as after ligature of the third part of the subclavian (p. 205). When the artery is tied near its termination the circulation is carried on by the anastomoses of the posterior circumflex with the superior profunda.

#### ANEURISM OF THE ARM, FOREARM, AND HAND.

Spontaneous aneurism rarely occurs in the upper extremity, below the axilla. G. Buchanan has recorded a case of spontaneous aneurism in the upper third of the brachial artery; Palletta, Flajani, Pelletan, and others, relate cases of spontaneous aneurism at the bend of the arm; and Liston states that he once tied the brachial artery in an old ship-carpenter, who whilst at work felt as if something had snapped in his arm. Pilcher has recorded a case of aneurism under the ball of the right thumb, which was produced by repeated though slight blows with the handle of a hammer used by the patient (a working goldsmith) in his trade; the radial and ulnar arteries were tied immediately above the wrist, and the disease was thus cured. Aneurism has also been met with in this situation after attempted reduction of a dislocation of the thumb. In the Museum of the College of Surgeons there is a preparation of a radial artery with a small aneurism, about the third of an inch in diameter, formed by the dilatation of all the coats of a narrow portion of one half the circumference of the vessel, a little above the origin of the *superficialis volæ*. Spontaneous aneurism in the forearm is extremely rare. Todd and Arnott both successfully tied the brachial in its upper third for spontaneous aneurism of the forearm. De Morgan records a case of spontaneous aneurism of the ulnar, and Spanton one of the radial artery. In most of the cases in which the brachial artery and its primary branches have been the seat of spontaneous

aneurism, disease of the heart and of the arterial system in other parts has co-existed.

While spontaneous aneurisms are rare in these situations, the traumatic forms of the disease are of more frequent occurrence (Vol. I., pp. 479-483).

**Treatment.**—In cases of aneurism below the axilla, direct pressure may be tried with advantage, provided the tumour be of small size and unattended with inflammation of the skin covering it. Compression of the trunk of the artery above the tumour is rarely applicable, on account of the pain that is induced by the pressure upon the neighbouring nerves, which cannot be isolated from the artery. Besides this, the brachial artery is so mobile, and the humerus so small and round, that the vessel cannot be steadily compressed against it for any length of time, but will roll away from under the pressure, even if the patient could bear the pain of it. The application of Esmarch's bandage under chloroform might be tried in suitable cases.

**Ligature of the Brachial Artery.**—The brachial artery may be ligatured

Fig. 490.—Line of Incision for Ligature of the Brachial in the middle of the arm.

in the *middle of the arm*, which is considered the seat of election by making an incision, about three inches long, parallel to and upon the inner edge of the biceps (Fig. 490), which is the "directing line," and the first rallying-point ;

Fig. 491.—Diagram of the parts concerned in Ligature of the Brachial in the middle of the arm. m.n. Median nerve drawn upwards; b, biceps; v, v. Veins; a, brachial artery.

the fascia, which is exposed, must be opened carefully to a corresponding extent, and the edge of the biceps drawn outwards, when the median nerve will commonly be seen crossing the artery ; this must be drawn on one side with a blunt hook, when the artery, accompanied by its two veins, will be exposed ; these vessels must then be separated from one another, and the ligature passed and tied in the usual way. In performing this operation, the principal point to attend to is to cut down upon the inner edge of the

biceps, which will be the sure guide to the artery (Fig. 491). If the Surgeon keep too far back, he may fall upon the ulnar nerve and the basilic vein, which might possibly be mistaken for the brachial artery ; by taking care to expose the fibres of the biceps in his early incision, he will avoid this error. The fascia over the median nerve must be opened thoroughly, otherwise the artery may be drawn on one side with it. The needle must be passed from the nerve.

In the *upper part of the arm* the operation for ligature of the brachial is practically identical with that for the terminal part of the axillary, the inner edge of the coraco-brachialis being taken as the directing line and the first rallying-point.

At the *bend of the elbow* the brachial artery may be reached by making an incision about two inches in length downwards and outwards parallel to and immediately above the median basilic vein when that vessel can be seen ; when it can not, the incision must be at an angle of  $45^{\circ}$  with the line of the limb, commencing about one inch external to and half an inch above the tip of the inner condyle of the humerus, and terminating at the outer side of the tendon of the biceps. It must not be carried further outwards or the median cephalic vein will be divided. If the median basilic vein is seen, it must be drawn downwards to avoid wounding the ulnar veins which enter it below. As soon as the integumental structures are divided, with the branches of the internal cutaneous nerve, the bicipital fascia comes into view. This must be carefully divided ; the artery will be found beneath, having the biceps tendon to its outer side, the median nerve to its inner side, and a vena comes on each side. The needle must be passed from the nerve. It sometimes happens that the operator misses the artery and comes down upon the brachialis anticus which lies beneath it. This muscle is readily recognized by its surface being composed at this part of alternate strips of tendon and muscular fibres. If circumstances require the operation to be performed a little higher up, the edge of the biceps must be taken as the guide, as in the middle of the forearm.

*Collateral circulation.*—When the brachial is ligatured *above the inferior profunda* the most important anastomosis is that between the superior profunda and the radial recurrent, anastomotica magna, and interosseous recurrent. If *below the inferior profunda*, there is in addition the anastomosis of this branch with the anterior and posterior ulnar recurrent and with the anastomotica. After ligature *at the bend of the elbow* the circulation is maintained by the anastomosis of the superior profunda, inferior profunda and anastomotica with all the recurrent branches from the forearm.

**Ligature of the Radial and Ulnar Arteries.**—These arteries may be ligatured at any part of their course, but the operation is never performed above the middle third of the arm except for direct wounds.

The **Ulnar Artery above the Wrist** may be readily ligatured by making an incision (Fig. 493) about two inches in length along the outer side of the tendon of the flexor carpi ulnaris, which is the directing line to the vessel. The incision should terminate about half an inch above the pisiform bone. If the edge of the tendon cannot be clearly felt, the incision must be made in the line of the artery. This is found by drawing a straight line from the tip of the inner condyle of the humerus to the radial edge of the pisiform bone. The first rallying-point is the edge of the tendon of the flexor ulnaris. As soon as this is clearly exposed it must be drawn inwards with a blunt hook, the wrist being slightly flexed to relax the muscle. A distinct fascia, usually marked by transverse fibres, then comes into view ; this must be carefully

Fig. 492.—Diagram of the Ulnar Artery at the Wrist. *fl.z.sub.*, flexor sublimis digitorum ; *fl.c.ul.*, flexor carpi ulnaris ; *v.u.*, vein ; *a.*, artery.

opened and the artery will be found beneath, accompanied by a vein on each side and the ulnar nerve on the ulnar side (Fig. 492). The needle must be passed from the inner side. The artery lies between the tendons of the flexor carpi ulnaris and of the flexor digitorum sublimis and upon those of the flexor profundus. The mistake most likely to be made is carrying the incision too far inwards so as to miss the tendon: the error is recognized by finding fleshy fibres directed downwards and outwards; the tendon is to the radial side of these.

**Ligature of the Ulnar Artery in the Middle of the Arm** is a more troublesome operation, as the artery lies deeply on the flexor profundus covered by the superficial muscles of the forearm. It can, however, be reached without difficulty by separating the flexor carpi ulnaris from the contiguous border of the flexor sublimis digitorum. To find the interval between these two muscles, a line must be drawn from the tip of the inner condyle of the humerus to the radial edge of the pisiform bone. This line corresponds to the outer edge of the flexor carpi ulnaris and also in its lower two thirds, to the course of the artery. The upper part of the artery passes beneath the

Fig. 492.—Lines of Incision for Ligature of the Brachial Artery at the bend of the elbow and the radial and ulnar arteries in the middle of the forearm and at the wrist.

superficial muscles of the forearm from the middle of the hollow in front of the forearm to the junction of the upper and middle thirds of the line just mentioned. The operation is thus performed: the guiding line having been found, an incision two inches in length is made in it (Fig. 493) through the skin and fat. A white line then comes into view formed by a few tendinous fibres in the edge of the flexor ulnaris. If more than one white line is seen a piece of ligature thread may be placed with one end on the inner condyle, and the other on the radial edge of the pisiform bone; the line corresponding to this is the one sought for. The point of the knife is then run lightly along the radial side of the line, after which the flexor sublimis and flexor ulnaris can easily be separated with the handle of the scalpel. The direction of the interspace is towards the ulna. On separating the muscles the artery may appear at once with a vein on each side of it lying on the flexor profundus. More commonly the ulnar nerve is first seen; when this comes into view, the flexor sublimis must be raised and drawn outwards, when the artery will be found coming out from beneath it to join the nerve lower down. The needle must be passed from the inner side. The common error in this operation consists in making the incision too much to the radial side and opening the interval between the flexor sublimis and the palmaris longus by mistake. The error is at once recognized by finding that the interspace leads towards the radius instead of the ulna.

The **Radial Artery above the Wrist** may be ligatured by making an incision about one and a half to two inches in length, a quarter of an inch outside the tendon of the flexor carpi radialis—the “directing line” (Fig. 493); after the division of the superficial and deep fasciæ, the artery accompanied by its two veins will be exposed, and may be tied in the usual way. The artery lies between the tendons of the flexor carpi radialis and supinator longus, and is separated by some fat from the pronator quadratus.

The **Radial Artery in the middle of the Forearm** can easily be ligatured by an incision made in a line drawn from the middle of the hollow in front of the elbow to the root of the styloid process (Fig. 493). At this part it is overlapped by the belly of the supinator longus, and lies on the insertion of the pronator teres. The incision should be about two inches in length; after the fascia is divided the supinator comes into view, its internal edge must be found and the muscle turned outwards. A distinct fascia is found beneath it, on opening which the artery will be seen with a vein on each side. The radial nerve is about half an inch to the outer side, and is usually not seen.

**Ligature of the Radial Artery at the Wrist** has sometimes been done for aneurism of the palm, but is more commonly required for wound. The artery at this part of its course lies deeply on the external lateral ligament of the wrist-joint. It winds round the lower end of the radius, passing beneath the extensor ossis metacarpi and extensor brevis pollicis, and then under the extensor longus pollicis. The operation is performed by making an incision from the base of the metacarpal bone of the thumb to the posterior part of the root of the styloid process of the radius in such a way as to be midway between the tendons of the long and short extensors of the thumb. In the superficial fat will be found the radial vein (which must not be mistaken for the artery) and some branches of the radial nerve. A fascia extending between the two tendons is then found and carefully opened, when the artery will be seen crossing the wound obliquely rather towards its lower end. This operation should never be performed in preference to that in front of the wrist, as it is more difficult and is apt to leave some stiffness in the tendons of the extensors of the thumb.

## CHAPTER XLV.

## ANEURISMS OF THE ABDOMEN AND LOWER EXTREMITIES.

## ANEURISM OF THE ABDOMINAL AORTA AND ITS BRANCHES.

**Aneurism of the Abdominal Aorta** is a rare affection, and is met with almost exclusively in men. It may occur at any part of its course, but the most common situation is near the origin of the coeliac axis; and here the disease is often not confined to the main trunk, but one or more of the branches are also affected. The situation next in order of frequency is at or near the bifurcation. Aneurisms may also form in connexion with any of the main branches of the abdominal aorta, most frequently on the superior mesenteric, splenic, and inferior mesenteric. The aneurism may be sacculated or tubular. When growing from the main trunk, it is usually sacculated.

**Symptoms.**—The chief sign of the disease is the existence of a pulsating tumour, situated in or near the middle line, somewhere between the costal margin and the umbilicus. The pulsation of the tumour is expansile, and there is frequently a distinct bruit. Walshe mentions a single systolic murmur, a dull muffled systolic sound convertible into a murmur by a little pressure, a sharp, abrupt, short systolic murmur on the left side of the lumbar spine, a systolic murmur audible below the sac, but not over it, and occasionally a dull second sound, as having been heard in various cases of abdominal aneurism. The exact shape and size of the tumour and the nature of its pulsation can in many cases be ascertained only by fully relaxing the abdominal muscles by an anæsthetic. The sensation of pulsation in the epigastrium may be very perceptible to the patient, or may be entirely absent. Constant aching lumbar pain is a very frequent symptom. The pressure-signs are not usually very marked till late in the disease. Pressure on the vena cava to such an extent as to cause œdema of the lower extremities is almost unknown. The sac may press on the lumbar plexus, and give rise to signs of irritation in the course of its branches. The most marked of these are pains in the groin and testicle from irritation of the genito-crural, and occasionally shooting pains down the thigh, in the course of the anterior crural or externa cutaneous nerve. When the bodies of the vertebræ are eroded, constant lumbar pain will frequently be present, of the same burning, boring character as that felt in thoracic aneurism under similar circumstances. In some cases the pressure may affect the great intestine, causing incomplete obstruction of the bowels. Occasionally the tumour may attain an enormous size before death, half filling the cavity of the abdomen. The fatal termination may be due to gradual exhaustion from pain and interference with the functions of the abdominal viscera, to sudden rupture of the sac into the peritoneum or subperitoneal tissue, or into some part of the alimentary canal, or, more rarely, into the pleural cavity through the diaphragm.

The **Diagnosis** rests chiefly on the situation of the tumour, its distinct expansile pulsation, the existence of an aneurismal bruit, and the pressure-signs. *Very marked epigastric pulsation* is not an unfrequent symptom in anæmic patients suffering from atonic dyspepsia, and in these cases very slight pressure on the artery with a stethoscope will give rise to a distinct bruit. Under these circumstances, it is sometimes not easy to speak positively as to the condition of the artery, but in the majority of cases a careful examination under an anæsthetic will determine the nature of the disease. A *displaced or enlarged heart* also gives rise to distinct epigastric pulsation, but this can hardly be mistaken for aneurism. A *solid mass of feces* in the transverse colon may receive a very distinct impulse from the aorta, but the doughy feel of the mass, its superficial nature, and the history of the case, will usually readily determine its nature. A *prominent lumbar vertebra* pushing the aorta forward may simulate a dilatation of the artery. *Enlarged lumbar glands* surrounding the artery may give rise to considerable difficulty in diagnosis; and here again a careful examination under an anæsthetic is the most likely means of arriving at a correct conclusion. *Sarcomatous tumours* growing from the *bones* may give rise to almost insuperable difficulties in the diagnosis. From *tumours of the various abdominal viscera* the diagnosis must be made on general principles. The amount of fat in the abdominal walls necessarily has a great influence on the difficulty or ease of coming to a definite conclusion.

**Treatment.**—In all cases of aneurism of the abdominal aorta, constitutional treatment should be given a fair trial before any more severe measures are adopted. Tufnell has recorded two cases in which a cure was effected by diet and rest—in one case in 21 days, and in the other in 37. If this treatment fail, the Surgeon may have recourse to **compression of the abdominal aorta**. The pain of this application is so severe that, in order to relieve it, the patient must be kept under the influence of chloroform; moreover, without thorough relaxation of the abdominal muscles it is impossible to employ it efficiently. The credit of introducing this mode of treatment is due to Murray of Newcastle-on-Tyne. The operation has now been performed for aortic aneurism in a considerable number of cases. Of six cases in which the pressure was applied on the proximal side of the sac, three—Murray's, Durham and Moxon's, and Greenhow and Hulke's—were successful; one, Pollock's, failed; and two, Durham's second case, and Paget's, were fatal. Of four cases in which pressure was applied on the distal side of the sac, one, under Bryant, and one under Lunn and Benham, terminated fatally, and the other two, under Marshall and Barwell, failed. In most cases the pressure has been applied by means of Lister's aortic tourniquet. That this instrument may in some cases be safely applied to the abdominal aorta from the highest point at which the artery can be reached to its bifurcation, is clearly proved by the results of the cases above mentioned. In Durham and Moxon's case, it is stated that "by positioning the body of the patient, just sufficient space was afforded for the introduction of the pad of the tourniquet between the cartilages of the ribs and the aneurism." In Greenhow and Hulke's case, it was applied midway between the xiphoid cartilage and the umbilicus, immediately above the tumour. That three out of the above ten cases have terminated fatally, however, shows that the operation is by no means devoid of danger. In Pollock's unsuccessful case the patient suffered from

hæmaturia, and in Greenhow's case albumen appeared in the urine after the last operation, thus showing serious interference with the circulation in the kidney. In Marshall's case the patient suffered from retention of urine for some days after one operation, probably from some injury to the hypogastric plexus. In Bryant's case the *post-mortem* examination showed bruising of the mesentery and intestine and peritonitis, and "the tissues about the compressed aorta were loaded with effused blood." In Lunn and Benham's case death occurred on the eleventh day from gangrene of the jejunum. In Paget's case an abscess had formed in the mesentery, peritonitis had been set up, and the mesenteric artery was found to be compressed and flattened, and embolic clots were found in its branches. In Durham's fatal case there were signs of bruising about the pancreas, and the aneurism was found to affect the mesenteric artery. The time during which the pressure has been maintained has varied considerably. Murray's case was cured by one application lasting five hours; Durham and Moxon's in 10½ hours; Greenhow and Hulke's, by three applications lasting 55 minutes, 4 hours, and 3 hours. In Marshall's case distal pressure was applied without serious consequences, on one occasion for 18 hours, and on another for 19 hours. Vomiting has been found to be a troublesome complication in several cases. Of the successful cases, Murray's is the only one in which the pulsation of the tumour ceased permanently immediately after the operation. In Greenhow and Hulke's case it did not finally disappear till some days after the last application of the tourniquet; and in Durham and Moxon's, although it ceased at the time, it returned in a few hours, and persisted for a month before it finally disappeared. From the above cases, it will be seen that there is sufficient probability of success to justify us in adopting the *proximal* operation in every favourable case. Further evidence is required before abandoning *distal* pressure as absolutely useless. In Bryant's fatal case the sac was found to be filled with firm clot, which was considered to have been sufficient, had the patient lived, to have cured the aneurism. In Marshall's case the tumour was thought to be slightly more solid after the operations, but no permanent effect was produced. The distal operation, however, does not seem a very hopeful one. The number and size of the branches coming off from the aorta at its upper part, and the frequency with which the coeliac axis and its large branches are implicated, are very unfavourable circumstances for distal pressure. The anastomosis of the collateral vessels is, moreover, so small compared to the immense interference with the direct circulation, that the only effect of distal pressure must be for many hours greatly to increase the tension in the vessels above.

In performing the operation of compression of the aorta under prolonged anaesthesia, a few points require special attention. The patient should be fed well on the day before the operation. On the day of the operation he should receive fluid nourishment only, and the bowels should be well emptied by means of a copious enema. The bladder also should be emptied. The tourniquet must be applied with the greatest care immediately above the tumour, and with no more force than is absolutely necessary. If much force be required before the pulsation in the femoral arteries is arrested, it is probable that the pad of the tourniquet is not in the right place, and various attempts must be made till the spot is found where the smallest amount of pressure will control the circulation. It will be found convenient to insert a soft hollow

sponge under the pad of the tourniquet, as it then accommodates itself more readily to the parts between it and the spine. During the operation the patient must be watched very carefully, and the tourniquet slackened at once if any symptoms of faintness supervene. Obstinate vomiting may render the continuance of the operation impossible. It is difficult to say whether this is due to pressure on the sympathetic or to the influence of the chloroform. During the application of the tourniquet, it is advisable to have the lower limbs raised in the bed and warmly wrapped in cotton-wool, as marked coldness and serious congestion have usually been noticed after the compression has lasted a short time. If necessary, nutritive enemata and brandy may be administered during the *anæsthesia*.

Abdominal aneurism has been treated in two cases by the introduction of foreign bodies into the sac after laparotomy, but without marked success (see p. 150), and in one case by acupuncture with improvement (see p. 151).

#### INGUINAL ANEURISM.

An **Iliac or Inguinal Aneurism** may arise from the external iliac, or from the common femoral artery ; most frequently it springs from the latter, and, taking a direction upwards, pushes the peritoneum before it, and thus encroaches somewhat upon the cavity of the abdomen. The aneurism is commonly sacculated, though sometimes tubular. It rarely if ever becomes diffused, for the reason long ago pointed out by Scarpa, that the femoral artery, above the edge of the sartorius muscle, is invested by so dense a sheath, and is so closely bound down to the neighbouring fascia, that, when dilated into an aneurism, it does not readily give way.

**Symptoms.**—When first noticed, the aneurism is a small, soft, compressible tumour, with pulsation and bruit, and is generally attended with little pain or uneasiness. It rapidly enlarges, however, and may attain a considerable size ; being often somewhat lobulated upon the surface, owing to the unequal constriction exercised on it by the fascia under which it lies. At the same time, it usually becomes more solid ; and the pulsation in it diminishes considerably, or even ceases entirely. As it increases in size, it compresses the saphenous and femoral veins, thus giving rise to œdema of the limb ; and, by stretching the genito-crural and some of the branches of the anterior crural nerve, it occasions considerable pain in the thigh and leg.

**Diagnosis.**—The diagnosis of inguinal aneurism is not always so easy as might at first appear. It has most frequently been confounded with abscess in the groin, and with soft pulsating sarcomata in this situation. The diagnosis from *abscess* must be made on general principles ; but in some instances it appears to be surrounded with difficulty, as there are not a few cases on record in which aneurisms in this situation have been mistaken for abscesses and punctured, an error that has three times fallen under my own observation, and one which has in every instance proved fatal. The diagnosis of an inguinal aneurism, solidified by the deposition of laminated fibrin, and pulsating but indistinctly, from a *pulsating sarcoma* in the groin, is surrounded by the greatest difficulty, and cannot, I believe, with the means we at present possess, be accomplished with absolute certainty. The fact of these diseases having in two instances been confounded by two of the most distinguished Surgeons

of their day, Stanley and Syne, is sufficient evidence of the difficulty attending the diagnosis.

**Treatment.**—It occasionally happens that inguinal aneurisms, even of a very large size, undergo spontaneous cure, or become consolidated by direct pressure conjoined with constitutional treatment; but this has so rarely occurred that such a result cannot be relied on in any one case.

**Treatment by Compression** has been successfully adopted in aneurism of the iliac arteries. Digital compression has been employed in several cases, but more commonly the pressure has been applied by Lister's abdominal tourniquet, Carte's compressor, Signorini's tourniquet or weights. In some cases the proximal pressure has been supplemented by distal compression of the femoral, or by the application of Esmarch's bandage to the limb. In whatever way the treatment is carried out, Murray insists on the importance of complete arrest of the flow of blood through the sac. It is usually necessary to administer an

Fig. 495.—Diagram showing the incisions in the following operations: *ELa* and *ELb*, Ligature of External Iliac according to Abernethy and according to Cooper. *L*, Abdominal Nephrectomy. *Laugenbuch's* incision. *O*, Ovariectomy. *S*, Gastrotomy.

anæsthetic during the treatment. The time required for consolidation in the successful cases has varied considerably. Thus, one of Murray's cases was cured in three-quarters of an hour, and one of Heath's (of Newcastle) in twenty minutes. In one under the care of Lawson, in which two tourniquets were applied—one to the abdominal aorta and one to the femoral below the sac—that on the aorta had to be removed at the end of twenty minutes, owing to collapse and vomiting; the femoral one being maintained in position. When the abdominal compressor was removed the pulsations had already diminished, and at the end of four hours they ceased, the patient making a good recovery. In other cases it has been necessary to continue the treatment intermittently for several days. Walsham has collected fifty-eight cases of inguinal aneurism from British and American sources occurring between 1870 and 1880. Treatment by pressure was adopted with success in 10. In 2 more the pulsation ceased, but the patients died shortly afterwards from rupture of an aortic aneurism. In 2 the treatment was directly the cause of death.

In 23 cases the artery was ligatured after pressure had failed, and in twelve of these Walsham is of opinion that the previous compression had rendered the conditions of the operation materially worse. These statistics show that in well selected cases compression holds out a fair prospect of curing the disease and should be tried before resorting to ligature, but care must be taken not to damage the vessel or the parts covering it by too prolonged or forcible efforts. Should it fail, it becomes necessary to tie the vessel leading to the sac. In the majority of instances the tumour, though it may have encroached on the abdomen, will not have reached too high for the external iliac to be ligatured ; should it have done so, however, the Surgeon may have to tie the common iliac artery ; but in some instances even this may not be

Fig. 496.—Ligature of the External Iliac by Abernethy's Operation, modified.

practicable, and his choice must lie between the slender chance offered by constitutional treatment, and the fearful alternative of ligaturing the aorta.

**Ligature of the External Iliac Artery.**—There are two modes of tying the external iliac artery without opening the peritoneum—the one originally practised by Abernethy, considerably modified by Liston ; and the other introduced by Astley Cooper.

*Abernethy's modified method* (Fig. 496) on the right side consists in commencing an incision at a point about one inch above and the same distance internal to the anterior superior spinous process of the ilium, carrying it in a curved direction, with the convexity outwards, to a point about three-quarters of an inch above and half-an-inch external to the middle of Poupart's ligament. When the operation is on the left side the incision should be commenced below

and carried upwards between the two points mentioned. The wound thus made is altogether external to the inguinal canal and to the line of the epigastric, and above and internal to the main trunk of the circumflex iliac artery. It is about four inches in length, and, if necessary, in fat subjects may be extended at the upper end. After cutting through the skin and superficial fascia, the tendon of the external oblique is carefully divided, as much as possible in the line of its fibres. The internal oblique and transversalis are next divided with great caution, when the transversalis fascia is reached, and recognized by its dull white appearance. Beneath this membrane there is often a little fat, especially at the lower part of the wound. A small portion of the fascia, at the lower end of the wound, is now carefully raised with the forceps, and cut through with the blade of the scalpel laid on the flat. A broad hernia director is then introduced, and passed underneath it, when it should be laid open to the full extent of the wound. In doing this care must be taken not to wound the peritoneum. This is most likely to happen in consequence of a fold of that membrane overlapping the end of the director, so that the knife wounds it when run along the groove. To avoid this it is safer not to push the knife quite to the end of the director. The risk of wounding the peritoneum may also be avoided by tearing the transversalis fascia with the fingers instead of using the knife. Both the fascia transversalis and the fascia iliaca are firmly attached to Poupart's ligament, so that there is no risk of stripping up the latter fascia in such a way as to displace the vessels. If a hole be made in the fascia transversalis large enough to admit the tips of the two forefingers, it will be found always to tear with the greatest ease to the full extent of the wound. When this is accomplished the whole inner side of the wound is drawn inwards and slightly downwards, the peritoneum being gently separated from its loose areolar connexions in the iliac fossa by the Surgeon's fingers; it must be kept out of the way by an assistant, who holds it up with a broad bent copper spatula. The artery will now be felt pulsating at the brim of the pelvis, and is readily brought into view at the bottom of the wound. It is enclosed in a very loose areolar sheath, and has the vein lying to its inner side and the genital branch of the genito-crural upon it. It is crossed near Poupart's ligament by the circumflex iliac vein. The investing areolar tissue must be scratched through, and the needle passed from the inner side between the vessels. When the artery is much diseased, it is often very tortuous, and may dip down into the pelvis so as to make it difficult to expose it except close to its lower end. Occasionally enlarged glands round the artery give some trouble by obscuring it and rendering it difficult to clean.

In *Astley Cooper's operation* the outer two-thirds of the inguinal canal are opened. An incision is made about three inches in length, beginning close to Poupart's ligament, about half an inch outside the external abdominal ring, and terminating about one inch internal to the anterior superior spinous process of the ilium. The line of incision is not quite parallel to Poupart's ligament, but rather to the fibres of the aponeurosis of the external oblique. In dividing the superficial fascia, the superficial epigastric artery is cut and must be ligatured. The external oblique having been exposed, a small hole is made through the aponeurosis at the lower end of the wound, and a director inserted, on which it is divided to the full extent of the wound, care being taken to cut exactly parallel to the fibres so as to injure the tendon as little as possible.

The knife may now be laid aside, the subsequent steps of the operation being carried out with a steel director and the forceps. The divided aponeurosis of the external oblique being held open with blunt hooks, the cord, surrounded by the cremaster, and the lower edge of the internal oblique come into view. Some loose areolar tissue and a few fibres of the cremaster must now be scratched through, close to Poupart's ligament, and the finger passed beneath the cord, which must be pushed upwards. The transversalis fascia is next carefully torn through with the director and forceps, and the artery can then be felt covered by a little fat and areolar tissue. Two copper spatulæ are next inserted through the opening in the transversalis fascia: the internal of these is drawn upwards and inwards, raising the cord and drawing the epigastric artery out of the way; the external pulls the lower border of the internal oblique and of the transversalis upwards and outwards. Both spatulæ raise the peritoneum. By clearing away a little loose areolar tissue, the artery can be exposed for one inch and a half or two inches without difficulty. It has the genital branch of the genito-crural lying on it, and it is crossed by the circumflex iliac vein a little above Poupart's ligament: the external iliac vein is to its inner side; these must be carefully avoided. The needle must be passed from the inner side not less than one inch above Poupart's ligament, so as to avoid the epigastric and circumflex iliac arteries. After the operation a drainage-tube may be inserted at the lower angle of the wound, and a catgut suture inserted in the divided tendon of the external oblique.

The *Collateral Circulation* after ligature of the external iliac is carried on by the following anastomoses: the deep epigastric with the internal mammary, intercostals, lumbar, and obturator; circumflex iliac with lumbar and ilio-lumbar; internal circumflex with obturator and sciatic; external and internal circumflex and perforating with gluteal; perforating with sciatic; external pudic with internal pudic.

On comparing the two operations, it would appear that the principal disadvantage of Abernethy's is, that it is apt to leave a tendency to hernia, in consequence of the abdominal wall being much weakened by the free incisions that are necessary through the muscular planes; the great advantage attending it is, that the external iliac may be ligatured at any part of its course, and that, if requisite, the incision may be extended upwards, and the common trunk secured. In Astley Cooper's operation, the line of incision lies directly across the course of the epigastric artery, which, as well as the circumflex iliac, if it arise high, and the circumflex iliac vein which crosses the iliac artery at this point and is often somewhat funnel-shaped, may be in danger of being wounded. The spermatic cord is likewise somewhat in the way in this operation. Dupuytren actually wounded the epigastric artery in one case; and Houston had much difficulty from the circumflex vein in another instance. This operation has also the disadvantage, that the incision upwards cannot be conveniently prolonged so as to tie any portion of the vessel except that which lies immediately above Poupart's ligament; but the peritoneum is less disturbed than in the other case, and there is less tendency to hernial protrusion afterwards. As a general rule, I think we may conclude that, in cases of spontaneous aneurism, in which it might, from the size of the tumour or the diseased state of the vessels, be found necessary to apply the ligature to a higher point than was intended before the operation commenced, it will be

safer to have recourse to Abernethy's plan, modified as above described, for in this way we shall be able to ligature the vessel at any part of its course ; whilst in cases of hæmorrhage after amputation, or of traumatic femoral aneurism, in which the artery is not likely to be diseased, recourse should be had to Cooper's operation, more particularly if the patient be thin, and the abdomen flat.

At the present day, however, the Surgeon may resort to ligature of the vessel through the peritoneum in those cases in which Astley Cooper's operation is impracticable. This plan is certainly to be recommended when it is doubtful whether it may not be found necessary to apply the ligature to the common trunk, for although Abernethy's incision may be extended for this purpose the procedure is a difficult one. Mitchell Banks, Coppinger, Makins, and Brown of Leeds have adopted the transperitoneal method successfully in cases of inguinal aneurism. In Banks's case the external iliac was tied through an incision in the right linea semilunaris. In Brown's case the aneurism extended so far above the groin that a median incision was employed ; the patient was very fat, and thus the operation was difficult.

In connexion with the ligature of the external iliac artery, there are some practical points that deserve mention. Before the operation the colon should be emptied by means of an enema, and the pubes shaved. The incision in the abdominal wall must be sufficiently extensive.

In Abernethy's method, modified as above described, there is no fear of wounding the epigastric unless the incision be carried too far at its lower end. The artery may roughly be said to run in a line drawn from the point at which the femoral artery crosses the brim of the pelvis to the umbilicus. In neither method of operating should the incision implicate the external ring, lest it give rise to a tendency to hernial protrusion. Care should be taken not to wound the peritoneum ; for, although with efficient antiseptic treatment there is little danger in so doing, yet it is better, if possible, to avoid it. The peritoneum must not be torn up more than is absolutely necessary, lest hæmorrhage or subsequent peritonitis occur. In raising the peritoneum, care must be taken not to displace the artery which lies loosely in the subperitoneal tissue, and can easily be raised in the spatula, or pushed over the brim of the pelvis. The separation of the peritoneum is much facilitated by the Surgeon holding the outer cut edge of the transversalis fascia tightly in his forceps with one hand, whilst with the other he gently raises the serous membrane out of the iliac fossa, and separates its areolar connections there. All this must be done with the utmost gentleness and care. Before attempting to pass a ligature round the vessel, the thin fascia covering it must be scratched through ; and the areolar connexions with the vein, which are very thin and loose, must be separated by means of a director, or the end of the aneurism needle. The artery must be well cleared, and especial care taken that the genital branch of the genito-crural nerve is not included in the noose. It is better not to use the knife deep in the wound. Lastly, the sac, if it extend high, must not be weakened by having its peritoneal covering stripped off.

**Results.**—Ligature of the external iliac was first practised by Abernethy in 1796. During the following fifty years there were 100 recorded cases of the operation for inguinal aneurism (Norris) ; of these 78 were cured and 27

died. Rabe's statistics, with 80 cases added by Barwell, give 141, with 31 deaths, or nearly 22 per cent.

Among the cases collected by Norris is one in which both external iliacs were ligatured successfully at an interval of eleven months by Tait.

In some few cases also, there was the complication of an aneurism in the ham with that in the groin. Of ninety-two cases in which the aneurism was seated solely in the groin, seventy were cured and twenty-two died. Death resulted from gangrene of the limb in eight, from secondary hæmorrhage in four, from sloughing of the sac in three, from tetanus in three, and from causes of a more general character in four cases.

*Pulsation returned in the sac* in six of the cases collected by Norris: in some not until several weeks had elapsed after the operation; and in one instance only was it followed by death. *Suppuration of the sac* was of frequent occurrence, happening in thirteen instances, doubtless owing to the large size of the tumour and to suppuration in the wound, which must necessarily in such cases be in close proximity to the sac. It is remarkable, however, that in three cases only was this accident fatal; and in two of these the sac had been opened before the operation, on the supposition of its being an abscess. *Secondary hæmorrhage* occurred in but six cases, four of which proved fatal; a very small proportion when compared with what happens in other situations. This must doubtless be attributed in a great measure to the absence of any collateral branches springing from the trunk of the external iliac; the distance between the point ligatured and the epigastric and circumflex iliac arteries affording abundant space for the safe obliteration of the vessel. In one of the fatal cases, pulsation had previously returned in the sac; in the other three the patients died on the seventeenth, the twenty-seventh, and the forty-third days respectively.

*Gangrene* of the limb was the most common cause of death in Norris's tables. It occurred in nine instances, of which eight proved fatal; one being cured by amputation. The period at which the gangrene occurred varied from the third to the fourth week. The principal cause of this gangrene is narrowing or obliteration of the neighbouring venous trunk, by pressure of the tumour. In the accompanying woodcut (Fig. 497) this is well illustrated; the vein opposite the aneurism being completely closed.

Rabe's statistics with Barwell's supplementary cases give somewhat different results. Hæmorrhage occurred in 24 of the 141 cases: of these 9 recovered and 15 died. Gangrene was fatal in 6, peritonitis in 2, retroperitoneal suppuration in 2, and various other causes in the remaining 6, making a total of 31 deaths in the 141 cases.

The ligature of the external iliac for *aneurismal varix in the groin* affords a

Fig. 497.—Obliteration of Femoral Vein by Inguinal Aneurism.

striking contrast with that for spontaneous aneurism ; the four cases recorded all proving fatal, two dying of gangrene, and two of hæmorrhage. In these cases Guthrie recommended that the tumour should be laid open, and the artery ligatured above and below the aperture in it. During the operation the artery may readily be commanded above the seat of disease by the application of the abdominal tourniquet, either to the aorta or to the common iliac at the brim of the pelvis.

Aneurism occasionally forms *in the groin and ham of the same side* ; here the ligature of the external iliac will cure both diseases. Of four cases in which this condition was present, the operation was successful in three ; one patient died of gangrene, a popliteal aneurism being on the point of bursting at the time of the operation. In two of the three cases that recovered, pulsation returned in the inguinal aneurism, but disappeared after a time.

**Ligature of the Common Iliac.**—This artery was first tied in 1812 by Gibson in a case of gunshot injury, the patient dying of peritonitis and secondary hæmorrhage on the thirteenth day. The great American Surgeon, Mott, was the first who tied it for aneurism, the patient making a good recovery. If the aneurism in the groin extend so high that there is not sufficient space for the exposure and ligature of the external iliac artery, it becomes necessary to tie the common trunk.

The most important points in the relations of the vessel are the following. The ordinary place of division of the abdominal aorta is on the body of the fourth lumbar vertebra, or on the intervertebral disk below it ; according to Quain, this was the case in four-fifths of the bodies he examined, or in 156 out of 196. In regard to the relations between the situation of the bifurcation of the aorta and the crest of the ilium, we find it, according to the same anatomist, to have ranged in about four-fifths of the cases between half an inch above and below the level of the highest point of this part of the bone. With reference to the umbilicus, no definite rule can be laid down ; but it may be stated broadly that the bifurcation of the aorta is a little to its left. As a general rule, that given by Hargrave is perhaps sufficiently good for ordinary purposes. If a point be taken about half or three-quarters of an inch below and a little to the left of the umbilicus, and a line be drawn on each side from this to another point midway between the symphysis pubis and the anterior superior iliac spine, we obtain about the direction of the common and external iliac arteries. On dividing these lines into three equal parts, the upper third will correspond to the common trunk, and the lower two-thirds to the external iliac, and the junction of the upper with the middle third to the bifurcation of the common iliac artery.

The point of bifurcation of the common iliac artery is, in the majority of cases, opposite the lumbo-sacral articulation ; and if it be not in this situation the division will probably be lower down. The length of the vessel varies greatly ; according to Quain, in five-sevenths of the cases it ranged between one-and-a-half and three inches.

The artery lies at the brim of the pelvis. The veins on the two sides differ in their relation to the arteries. The left vein lies to the inner side of the left artery, and then passes beneath the right common iliac artery to join the right vein in forming the vena cava inferior. On the right side the vein is at first beneath and then to the outer side. The common iliac artery is crossed by the ureter near its lower end.

The artery may be reached by an incision similar to that employed for the external iliac, or through the peritoneal cavity.

*Extraperitoneal Method.*—This may be done by extending the incision used by Abernethy for the ligature of the external iliac upwards and slightly inwards towards the umbilicus, to an extent corresponding to the degree of obesity of the patient, so that it assumes a somewhat similar form. If the operation is commenced with the intention of applying a ligature to the common trunk, the incision should be made from a point about one inch external to and one inch above the middle of Poupart's ligament in a curved direction to another point about two inches above and the same distance internal to the anterior superior iliac spine. The curve must be such that if prolonged the incision would reach a point about midway between the xiphoid cartilage and the umbilicus. Care must be taken that the incision be not carried too low down or too far forwards; nothing can be gained by doing so, and there is besides the additional risk of the circumflex iliac or epigastric being wounded, as happened to Mott; and as these are the principal agents in the anastomosing circulation, their injury is a serious accident. The muscles are carefully divided, as in the operation for tying the external iliac, and the transversalis fascia opened in the same way. The peritoneum now comes bulging into the wound, pressed forward by its contents. It must be gently stripped from the iliac fossa by the Surgeon carefully insinuating his hand beneath it, care being taken to raise it directly inwards towards the brim of the pelvis, at which point the external iliac will be found, which serves as a guide to the common trunk. The ureter always comes up with the peritoneum, and is usually not seen. The peritoneum must be well drawn inwards by broad copper spatulæ. The ligature must be passed round the artery on the left side from within outwards, a slight scratch having been made through the fascia covering the vessel by means of the finger-nail, by which it may also be separated from the accompanying vein. On the right side great caution must be used, on account of the position of the left vein beneath the artery and the right to its outer side. In the later stages of the operation, the patient should be turned on his sound side in order to prevent the intestines falling over and pressing the peritoneum into the wound.

*Transperitoneal Method.*—The difficult operation above described was fully justified when it was necessary at all costs to avoid opening the peritoneal cavity. Since, however, laparotomy, performed with proper antiseptic precautions, has come to be regarded as almost free from danger, the only serious objection to the exposure of the common iliac artery through the peritoneum has been removed, and in future cases the transperitoneal method is likely to be employed. In the preparation of the patient it is essential that the intestines should be emptied by the use of aperients and enemata. The bladder also should be empty and the pubes shaved. The abdomen is opened by a median incision below the umbilicus and the intestines are drawn aside with sponges and retractors. The peritoneum covering the artery is divided and in passing the needle care must be taken not to wound the vein or include the ureter or the sympathetic fibres which accompany the vessel. A strong light thrown into the wound is very essential. Of the cases in which this operation has been performed may be mentioned one by Fluhrer, in which death occurred on the 7th day from acute nephritis, and a successful case by

Clement Lucas, who tied the artery for a rapidly increasing aneurism of the external iliac.

The *Collateral Circulation* after ligature of the common iliac is carried on by the anastomoses of the circumflex iliac with the lumbar : deep epigastric with the internal mammary, lumbar, and intercostal ; the middle sacral with the lateral sacral ; the lumbar with ilio-lumbar ; superior with middle and inferior hæmorrhoidal ; obturator and visceral branches of internal iliac with those of the opposite side.

**Results.**—The earlier cases of ligature of the common iliac for aneurism were singularly successful, 7 out of 11 recovering up to 1852. Since that time the operation has frequently been repeated, but with less satisfactory results. Stephen Smith in 1860 collected the records of 32 cases in which this artery had been tied, of which only 8 recovered. Agnew in 1878 gives a table of 62 cases, of which 50 died and 12 recovered ; but Kummell in 1884 considered only 55 to be recorded with sufficient accuracy to justify their being included in a statistical table. Of these 41 died and 14 recovered ; in 16 the artery was tied for hæmorrhage, and of these 13 died ; in 32 for aneurism, with 22 deaths, and in the remaining 7 for vascular tumours and other causes, and of these 6 died. Gangrene has been a very rare cause of death after ligature of the common iliac.

The **Old Operation** has been performed in more than one case of iliac aneurism, when owing to special circumstances it was not possible to tie the artery above the sac. In Syme's well known case the sac was laid open and three ligatures applied, which were believed to include the external, internal, and common iliac arteries. The patient practically recovered, but died of pleurisy after some months, before leaving the hospital. The *post-mortem* examination showed that the ligatures had been placed on the external iliac. Astley Cooper attempted the same operation in the case in which he subsequently tied the aorta. Heath laid open the sac of an iliac aneurism which had been opened by mistake for an abscess before being admitted into University College Hospital. The external iliac was tied from within the sac, but the patient died from secondary hæmorrhage. The old operation can be performed with safety only when it is possible to compress the aorta above the sac ; and consequently, as Holmes points out, an attempt should be made to effect a cure by compression before so dangerous an operation is attempted.

**Ligature of the Aorta.**—It is impossible not to contemplate with admiration the man whose mind was the first to conceive, and whose hand was the first to carry out, the application of a ligature to the abdominal aorta ; and who, guided by pathological observation and physiological experiment, ventured to arrest at once the circulation through the main channel of supply to the lower half of the body, trusting to the collateral circulation for the maintenance of the vitality of the parts thus suddenly deprived of blood. Astley Cooper was the first to place a ligature on the aorta, in 1817. Since that period the operation has been six times performed for aneurism : viz., by James, of Exeter ; by Murray, at the Cape of Good Hope ; by Monteiro, at Rio de Janeiro ; by South, of London ; by McGuire, of Richmond, U.S. ; by Stokes, of Dublin ; and three times, in circumstances which will presently be described, by Czerny of Heidelberg, and Watson of Edinburgh.

TABLE OF CASES OF LIGATURE OF ABDOMINAL AORTA FOR ANEURISM.

NUMBER.	SEX.	AGE.	DATE.	NATURE OF ANEURISM.	OPERATIONS.	RESULTS.
1. ASTLEY COOPER	M.	38	1817	Diffused Inguinal	Incision through Peritoneum.	Death in 40 hours.
2. JAMES.	M.	44	1829	External Iliac.	Distal ligature first : Peritoneum opened.	Death in a few hours.
3. MURRAY.	M.		1834	Inguinal.	Aorta tied behind Peritoneum.	Death in 24 hours.
4. MONTEIRO.	M.		1842	Diffused Inguinal	Aorta tied behind Peritoneum.	Death on 10th day.
5. SOUTH.	M.	28	1856	Common Iliac.	Aorta tied behind Peritoneum.	Death in 43 hours.
6. MCGUIRE.	M.	30	1868	Lower part of Aorta, both Common Iliacs, and Left External Iliac.	Aorta tied behind Peritoneum.	Death in 12 hours.
7. W. STOKES.	M.	50	1869	Iliac.	Aorta tied behind Peritoneum.	Death in 13 hours.

In Astley Cooper's case, the inguinal aneurism had burst, and the aorta was tied about three-quarters of an inch above its bifurcation, by making an incision three inches in length through the abdomen, a little to the left of the umbilicus, the fingers being passed between the coils of the intestines, and the peritoneum covering the artery being scratched through. The patient survived forty hours. James ligatured the aorta much in the same way as Cooper, in a case in which he had previously employed the distal operation for an inguinal aneurism; but without success, the patient speedily dying. Murray ligatured the vessel by making an incision on the left side, in front of the projecting end of the tenth rib, and carrying it downwards for six inches to the anterior superior spine of the ilium. The parts were then carefully divided to the peritoneum, which was separated from the iliac fossa and the ~~psoas~~ muscle, when, with great difficulty, and by scratching with the end of an elevator and the finger-nails, room was made for the passage of the ligature round the artery, which was tied three or four lines above its bifurcation. The patient died in twenty-three hours. The most interesting case on record is that by Monteiro, who tied the aorta for a large false aneurism on the lower and right side of the abdomen; here the incision was made much as in Murray's case, and the artery ligatured with great difficulty. The patient lived till the tenth day, when he died of secondary hæmorrhage. In South's case, the aorta was tied behind the peritoneum by an incision on the left side of the abdomen. The patient died in forty-three hours. McGuire's patient had an aneurismal tumour of the size of a goose's egg in the left iliac region. Digital pressure near the umbilicus was attempted, but could not be done. The operator's intention was at first to tie the left common iliac artery; but, finding the disease more extensive than he expected, he enlarged the incision and tied the

aorta. The sac burst during the manipulation necessary to reach the aorta, and about a pint of blood was lost. The patient died in eleven hours. Stokes compressed the aorta with a silver wire passed round it in the way of a ligature. He made a crescentic incision five-and-a-half inches in length in the left side of the abdomen, extending from an inch below the tenth rib to the middle of Poupart's ligament. The abdominal muscles and fascia transversalis were then incised, and the peritoneum exposed and drawn out of the iliac fossa. It was accidentally, but only slightly wounded. The patient being turned on his right side, the arteries and the aneurism were exposed, and the wire passed by means of an aneurism needle round the aorta immediately above its bifurcation. The patient died in twelve hours. Perhaps the most interesting point in this remarkable case is the fact of the pulsation having returned in the left (sound) femoral artery nine hours after the operation; shewing how rapidly the collateral circulation can be established.

The following cases scarcely belong to the present category, but may be mentioned here. One was a French soldier, the upper part of whose thigh had been shattered by a ball at Weissenburg during the Franco-German war. Secondary hæmorrhage occurring, Czerny, then Billroth's assistant, tied the common femoral, and also the superficial femoral below the origin of the profunda. This arrested the hæmorrhage for a time; but in six days it recurred. Czerny then tied the common iliac; but, as the hæmorrhage continued, he thought that he had tied the external iliac, and proceeded to apply another ligature—which he placed by mistake on the aorta. The patient survived twenty-six hours. In this case too, twenty-two hours after the operation, the injured limb was cold and as if dead, while the opposite limb was warm, and retained sensation and motion. In another case Heron Watson tied the abdominal aorta by the transperitoneal method for secondary hæmorrhage following ligature of the common iliac; the patient died of exhaustion in sixty-three hours. Lastly, the aorta was unsuccessfully tied by Czerny for the arrest of hæmorrhage during the excision of a tumour of the kidney; the patient died in ten hours.

At the present day peritonitis can almost certainly be prevented, and the use of more suitable ligatures may add to the chance of success; but it appears to me that a patient suffering from an inguinal aneurism large enough to justify ligature of the aorta would have a better chance of recovery, or rather of prolongation of life, by the adoption of proper constitutional treatment, together with pressure upon the tumour and the distal ligature or compression of the artery. Lister's aortic compressor might be applied in such cases, so as to moderate the flow of blood. Should the operation be attempted again, there is little doubt that the incision adopted by Astley Cooper would be the safest, as the danger of peritonitis is much less under the present modes of treatment.

ANEURISM OF THE INTERNAL ILIAC AND ITS BRANCHES.—Aneurism of the *Trunk of the Internal Iliac Artery* is extremely rare. The only case with which I am acquainted is one related by Sundifort. The three principal branches of this artery—the *Gluteal*, the *Sciatic*, and the *Pudic*—have all occasionally, though rarely, been found affected by this disease. Of these branches the gluteal has most frequently been found aneurismal, the sciatic next, and the pudic least frequently; indeed, I am acquainted with only one instance of aneurism of this vessel. It is the preparation 1701 in the Museum of the

College of Surgeons : and it exhibits an aneurism of the trunk of the pudic nearly an inch in diameter, full of laminated clot.

**Aneurisms of the Gluteal and Sciatic Arteries** may be either traumatic or spontaneous.

Fischer of Hanover has published with comments, in the *Archiv für klinische Chirurgie*, the records of thirty-five cases of gluteal and sciatic aneurism ; to which must be added a case of gluteal aneurism described by Gallozzi of Naples, one by Bickersteth of Liverpool, and three by Dennis. In twenty-seven of Fischer's cases the aneurism was gluteal, in six sciatic, and in two the origin was uncertain. Thirteen of the gluteal aneurisms, and two of the sciatic, were of traumatic origin ; fourteen gluteal and four sciatic aneurisms were spontaneous. The gluteal aneurism has generally been found situated on the upper part of the great sciatic notch ; but it may extend over a large portion of the buttock. Sciatic aneurism lies more deeply ; and a portion of the sac may be within the pelvis. The size of these aneurisms varies from a slight swelling to a tumour as large as a child's head. In almost all the recorded cases there has been strong pulsation, with whirring and buzzing murmurs heard on auscultation. There is almost always pain in the tumour itself and in the course of the sciatic nerve, which may be followed by paralysis of the parts supplied by it.

The affections with which these aneurisms are most likely to be confounded are abscesses, soft sarcomata, cysts, and sciatic hernia. The diagnosis is sometimes difficult : thus Guthrie ligatured the common iliac artery for a large pulsating tumour in the gluteal region, which presented all the characters of aneurism, but which proved, on the death of the patient eight months after the operation, to be a sarcoma. The diagnosis may be facilitated by examination through the rectum, as the sac may lie partly in the pelvis.

Gluteal aneurisms have on several occasions been opened by mistake for abscesses. According to Holmes, this accident has most frequently happened when the aneurism has been more or less diffused, and in such cases he suggests that the aspirator should be used to render the diagnosis certain.

In the **Treatment**, various methods have been employed. *The sac has been laid open* and the gluteal artery tied in five cases, all of which recovered. In another instance, after laying open the sac, the aneurism (gluteal) was found to extend into the pelvis ; and the internal iliac artery was tied, with a fatal result. *Ligature of the internal iliac artery* has been performed in fourteen cases, eight of which recovered. *The common iliac artery* has been tied in three cases, all of which proved fatal. *Injection of the perchloride of iron* has been used in six cases ; four recovered, one died, and in one the result is not known. *Ligature of the sciatic artery* without opening the sac has been performed in two cases, one of which recovered. Spontaneous recovery is reported to have occurred in one case.

**Ligature of the Internal Iliac.**—This vessel was ligatured for the first time in 1812. The operation was performed by Stevens of Ste. Croix, on a negro who suffered from an aneurism of the nates, supposed to be of the gluteal artery, but found after death three years subsequently to take its origin from the sciatic. Stevens in this case made an incision five inches long on the left side of the abdomen, carefully dissected through the parietes, separating the peritoneum from the iliac fossa, turned it on one side, together with the ureter, and passed a ligature round the artery without much diffi-

culty. Since that time the operation has been done twenty-four times : in nine cases with success, by Arndt, White, Mott, Syme, Morton, Gallozzi, Chew, Dennis and Treves ; in fifteen cases unsuccessfully, by Atkinson, of York (whose patient died on the nineteenth day, of secondary hæmorrhage), by Bigelow, Torracchi, Cianflone, Porta, Landi, Kimball, Altmüller, Thomas, J. K. Rodgers, Higginson and Dennis ; and three times by the Surgeons in the American Civil War.

The success that has hitherto attended this operation is certainly remarkable, when we take into consideration the depth at which the artery is situated and its great size ; it may, I think, be accounted for in part by the fact that, although in these cases the patient runs the ordinary risk attendant on the ligature of the larger pelvic arteries from the exposure and handling of the peritoneum, yet he is saved from danger resulting from the supervention of gangrene ; the anastomosis being so free, and the course traversed by the blood so short, that no difficulty can arise in the maintenance of the collateral circulation.

The internal iliac artery may be exposed by methods precisely analogous to those used for the ligature of the common trunk. When the vessel is reached it must be remembered that both the external and internal iliac veins are in close relation to it ; the one being to its outer side, the other behind it. As those vessels are large, and their coats thin, it is necessary that they should be separated by the finger-nail, or the blunt end of the aneurism needle, before the ligature is passed round the artery ; care must be taken also not to put the vessel too much on the stretch in applying the ligature, lest the ilio-lumbar artery be ruptured. There is little risk of including the ureter which crosses the artery internally as it always adheres firmly to the peritoneum and is pushed on one side with it. As the length of the artery varies much, usually ranging between one and two inches, and as when it is short it has a tendency to be placed deeply in the pelvis, it would, I think, be more prudent, and occasion less chance of secondary hæmorrhage, for the Surgeon to ligature the common trunk.

The transperitoneal method is likely to be the only one employed in future cases, and the steps are the same as for ligature of the common iliac (p. 230). It has hitherto been put in practice at least four times. In the first case, Dennis opened the abdomen and applied a catgut ligature to each internal iliac artery in a case of double gluteal aneurism. The intestines were held on one side by warm sponges and cloths, and the arteries easily exposed by dividing the peritoneum covering them. The operation lasted about 30 minutes. The patient, a female, never completely rallied from the operation, and died on the fourth day from suppression of urine. There was no peritonitis. In the second case, Chew opened the abdomen in the line of the usual incision for ligature of the internal iliac, and the patient, a negro aged 46, rapidly recovered. In the third case, Dennis successfully tied the artery, opening the abdomen in the linea alba. In a fourth case Treves tied the artery with success in a case of vascular tumour of the buttock. The patient was a boy, aged sixteen, and the artery was reached through a median incision below the umbilicus.

#### FEMORAL AND POPLITEAL ANEURISMS.

Aneurisms of the thigh are much rarer than those affecting the groin, but those in the ham are relatively much more common. Thus out of 551 cases

of aneurism recorded in the British medical journals of the present century, Crisp has found that 137 affected the popliteal, and only 66 the femoral artery. Of these 66, 45 were situated either in the groin or upper part of the thigh, and 21 only were truly femoral or femoro-popliteal. The reason of this difference in the frequency of the occurrence of aneurism in different parts of the vessel, may be accounted for by its anatomical relations. In looking at the main artery of the lower extremity, in its course from Poupart's ligament to where it terminates in the anterior and posterior tibials, we see that it may be divided in relation to the muscular masses that surround it, into three principal portions: 1. That which is situated between Poupart's ligament and the inner margin of the sartorius, and which may be considered *inguinal*; 2. That which intervenes between this point and the aperture in the adductor tendon, and which may be considered *femoral*; and, 3. That division of the vessel which corresponds to the ham, and which may be considered *popliteal*. Of these three divisions, the first and last are comparatively superficial, and, being unsupported by muscle, readily expand; while the central portion of the artery is closely surrounded on all sides by muscular masses, and is very unlikely to be dilated into an aneurismal tumour. We find also that the inguinal portion of the vessel is closely and firmly invested by a dense and resistant fibro-areolar sheath, and is well supported by the fascia lata; whilst in the popliteal space the artery is surrounded merely by the ordinary areolar sheath, and receives no aponeurotic support. This difference in the connexions of these two parts of the vessel may, to a certain extent, explain the greater frequency of aneurism in the ham than in the upper part of the thigh. Lastly, the constant movements of the knee-joint doubtless favour the occurrence of aneurism of the popliteal artery.

ANEURISM OF THE DEEP FEMORAL ARTERY is extremely rare; indeed, I am acquainted with only six cases. One of these occurred in a young man under my care in University College Hospital in 1870. There was a large tumour at the upper part of the thigh, over which lay the superficial femoral artery, pulsating freely. The disease was cured by compression of the common femoral artery, hydrate of chloral being given to relieve pain. Another case is recorded by Bryant as having occurred in the practice of Cock at Guy's Hospital. The aneurism was situated at the origin of the deep femoral artery; the external iliac was tied, but the patient died nine weeks after the operation. Fig. 498 is taken from a patient who died of pneumonia shortly after admission into University College Hospital. On examination after death, a large tumour of the thigh, which had not been very closely examined during life, proved to be a false aneurism apparently arising from rupture of a perforating artery, most probably the consequence of embolism (Univ. Coll. Museum, 1274). Two cases are recorded by P. Marshall and J. Watson. Another has occurred under the care of C. H. Golding-Bird. The tumour had

Fig. 498.—False Aneurism of a Perforating Artery.

1. Common Femoral.
2. Superficial Femoral.
3. Deep Femoral.
4. Aneurism, cut open.

been noticed for three months and had been rapidly extending for five weeks. It filled the front and inner side of the upper third of the thigh, and extended for three inches into the iliac fossa. The external iliac and common femoral were pushed inwards two inches. The external iliac was tied but the patient died on the fifth day of pneumonia. In the case which was under my care in the Hospital, the disease was recognized by the following signs, which are characteristic of it : 1. A large tumour extended from three inches below Poupart's ligament to the middle of the thigh, raising and slightly separating the adductor muscles and the rectus femoris. 2. All the ordinary aneurismal signs were present in this tumour—the most marked being a peculiarly loud and harsh bruit, and a dry forcible thrill. 3. The superficial femoral artery could be felt running over the anterior and inner aspect of the tumour, but distinct from it. 4. The pulsation in the popliteal and its divisions was normal. 5. All the aneurismal signs ceased on compressing the common femoral artery, and returned on removing the pressure.

The only disease with which an aneurism of the deep femoral artery can readily be confounded is pulsating sarcoma of the femur. The diagnosis from this must be left to the surgical tact of the practitioner.

In the **Treatment** of these aneurisms, the Surgeon has the choice of three methods : viz., compression in the groin, and ligature of the external iliac, or of the common femoral. If the common femoral ever should be ligatured for aneurism, this appears to me to be the case best suited for it. But the choice between the ligature of this artery or of the external iliac must in a great measure depend upon the Surgeon's judgment as to the relative expediency of either operation, and on the height to which the aneurism extends up the groin. But neither artery should be ligatured until compression has been fairly tried and has failed. This may be done digitally or by Carte's instrument, where the artery passes over the brim of the pelvis. It is especially likely to succeed in aneurism of the profunda, owing to the shortness of the trunk and the way in which it breaks up into many anastomosing branches. Hence there is not a free current of blood passing from one large vessel of entry to another of exit, but, as it is broken up and has to filter out through a number of minor vessels, its coagulation may readily be brought about. In the case treated by me, compression effected a cure in twenty-four hours, though the aneurism was very large and active.

**ANEURISMS OF THE SUPERFICIAL FEMORAL AND POPLITEAL ARTERIES.**—These occur commonly about the middle period of life, and are almost invariably met with in males, being at least twenty times more frequent in them than in women. Both sides are affected with equal frequency, and occasionally at the same time. According to Crisp, sailors would appear to be more liable to this variety of the disease than any other class. These aneurisms are most frequently sacculated ; in the ham they are always so, but in the thigh they are sometimes tubular.

**Symptoms.**—The symptoms of **Femoral Aneurism** present nothing peculiar : the tumour usually enlarging with considerable rapidity, with all the characteristic signs of the disease, and assuming a more or less regular ovoid shape. **Popliteal Aneurism** usually commences with stiffness and a good deal of pain about the ham and knee, which I have more than once seen mistaken for rheumatism ; in fact, so commonly does this happen that the

Surgeon should never fail to pass his hand behind and examine the ham in every case of persistent "rheumatic" pain in the knee. There is also a difficulty in straightening the limb, which is generally kept semi-flexed. The tumour increases usually with great rapidity, and has a tendency to become diffused; these conditions will, however, materially depend on the side of the artery from which it springs. When it arises from the anterior aspect, next the bone, it increases slowly, being compressed by the firm structures before it. In this case, however, there is the great danger that, by its pressure upon the bones and knee, it may give rise to caries and destruction of the joint. When it springs from the posterior part of the artery, where it is uncompressed, it increases rapidly, and may speedily become diffuse. The diffusion of an aneurism in this situation may take place in two directions. If it be femoro-popliteal, it may give way into the general areolar tissue of the thigh, the blood diffusing itself as high perhaps as Scarpa's triangle. When it is confined to the ham, it may give way either under the integuments and into the superficial structures of the limb, or else under the deep fascia of the leg, where it will compress the posterior tibial nerve and artery. In all cases, the diffusion of popliteal aneurism is likely to be followed by gangrene.

**Diagnosis.**—The diagnosis of popliteal aneurism has to be made from chronic abscess, from bursal enlargements, and from solid tumours. In distinguishing it from *chronic abscess* no serious difficulty will be experienced; but it may happen that, when an aneurism has suppurated, considerable difficulty may arise in determining its true nature—whether it be merely an abscess or not. On such cases as these, the state of the circulation in the lower part of the limb will throw much light. *Bursal tumours*, often of large size and multilocular, are not unfrequently met with in the ham; but I have never found any great difficulty in determining their true nature—their elasticity and roundness, together with their mobility and want of pulsation, being sufficiently indicative of their character. The most serious difficulty may arise from confounding consolidated aneurisms of the ham with *solid tumours*, of a sarcomatous character, springing from the tibia and femur; and I have known one case of aneurism in this condition, in which amputation was performed on the supposition of its being a solid tumour (Fig. 451).

**Treatment.**—The treatment of femoral and popliteal aneurism may be conducted either by compression or by ligature of the vessel leading to the sac. As a general rule, for the reasons already stated, compression should be employed in preference to ligature; but cases do arise in which, from the failure of compression, or for other reasons, it becomes necessary to ligature the femoral artery.

The Treatment by **Compression** is peculiarly applicable to these aneurisms, and indeed it is for them that it has chiefly been employed. I need, therefore, say nothing special about them here, but would refer the reader to Chapter XLIII, page 134, for a description of the subject.

**Flexion** of the knee, which may be considered a modification of compression, is applicable to these cases also, either alone or in combination with compression of the main trunk. It is peculiarly applicable in those cases in which the aneurism is situate entirely in the ham (see p. 145).

**Ligature of the Common Femoral.**—In looking at the femoral artery might at first be supposed that the common trunk, situated superficially between Poupart's ligament and the origin of the profunda, would be the most

convenient situation for the application of the ligature; but experience has shown that deligation of the vessel here is by no means a successful operation, especially when undertaken for aneurism. This arises from the shortness of the trunk rendering it necessary to tie the artery in close proximity to the collateral branch that will constitute the most direct and immediate agent in the anastomosing supply,—viz., the deep femoral, so that the internal coagulum would not readily form. In addition to this, a number of small inguinal branches, the superficial epigastric and circumflex iliac, the superior and inferior external pudic, and very commonly one of the circumflex arteries of the thigh, more especially the internal, arise from the common trunk in its short course; and these vessels, though small in size, constitute a source of great embarrassment to the Surgeon during the operation; for, if wounded near their origin, they bleed furiously, and are a cause of subsequent danger, by interfering with the proper plugging of the vessel. The ligature of the common femoral has, however, had several advocates, more particularly in Ireland, where the operation has been done nine times, for wound and aneurism, with six recoveries and three deaths. The successful cases were as follows: Porter, sen., three; G. H. Porter, one; Smyly, one; Macnamara, one. In the American War, however, the operation is reported to have been performed in eighteen cases with only four recoveries; and Barwell states that out of thirty-one cases in which the artery was tied for aneurism, hæmorrhage occurred in eighteen, and of these twelve died.

The vessel may be reached by a vertical or a transverse incision; of these the former is preferable. The incision commences at Poupart's ligament, at a point midway between the symphysis pubis and the anterior superior iliac spine, and is carried downwards in the line of the artery for about two inches; the skin, fat, and superficial fascia are divided, and the lymphatic glands removed or turned on one side. The fascia lata is then divided, and the crural sheath exposed. This must carefully be opened over the artery, and the needle passed from the inner side. The femoral vein lies to the inner side, and the anterior crural nerve a short distance away on the other side. The origin of the branches is very uncertain; the Surgeon must select that part of the vessel for ligature which is most distant from any branch.

The statistics of this operation are so unfavourable, especially when performed for aneurism, and secondary hæmorrhage has been so frequent and fatal an occurrence, that I do not think it advisable to have recourse to this operation in preference to ligature of the external iliac; and it may be laid down as a rule in surgery, that in all those cases of aneurism that are situated above the middle of the thigh, in which compression has failed and sufficient space does not intervene between the origin of the deep femoral and the upper part of the sac for the application of a ligature to the superficial femoral, the external iliac should be tied.

**Ligature of the Superficial Femoral.**—The superficial femoral artery, in its course from the origin of the profunda to the aperture in the tendon of the adductor magnus, is divided by the sartorius into two portions of unequal length, which have different relations to neighbouring structures. The upper division of the artery, which lies above the inner margin of the muscle, is of most interest to the Surgeon, as it is in this part of its course that it is invariably ligatured in cases of aneurism. It is true that John Hunter, in the operation which he introduced for popliteal aneurism, exposed

and tied the vessel in the middle third of the thigh ; but his example has not been followed by modern Surgeons, on account of the far greater difficulty in reaching the vessel here than in the first part of its course. The superficial femoral, where it lies in Scarpa's triangle, being covered merely by the integument, the superficial fascia and the fascia lata, may be reached by as simple an operation as any that the Surgeon has to perform for the ligature of the larger vessels. The line to the artery is taken as follows : The leg is flexed and the thigh rotated outwards. The Surgeon marks a point exactly midway between the anterior superior spine of the ilium and the symphysis pubis. From this he draws a line to the most prominent part of the inner condyle of the femur. The point selected for tying the artery must be about five inches below Poupart's ligament, as the ligature will then be at a safe distance from the profunda, the lowest recorded point of origin of that

Fig. 499.—Ligature of the Superficial Femoral Artery.

vessel being four inches below the ligament. The incision (Fig. 499) is made in the line above indicated, and should be from three to six inches in length, according to the amount of subcutaneous fat. It must be so arranged that the point selected for the application of the ligature shall be in the middle of its length. The skin and superficial fascia having been divided, the fascia lata is exposed and opened to the same extent as the incision in the integuments ; the muscular fibres of the sartorius now come into view. If the incision have been made too far inwards, it is possible that the adductor longus may be exposed instead of the sartorius ; the error is readily recognized by observing the direction of the fibres, those of the adductor being downwards and outwards, and those of the sartorius downwards and inwards. The edges of the wound in the fascia being held apart with blunt hooks, the sartorius is seized in the forceps and drawn outwards, the fibres of the areolar tissue

surrounding it being touched with the edge of the scalpel, if necessary, until its inner edge comes into view. If the operation be performed a little higher than usual, or if the sartorius be feebly developed, its inner edge may come into view as soon as the fascia lata is divided. The edge having been found, the muscle must be turned outwards and held on one side with a copper spatula. A little loose areolar tissue must then be cleared away from beneath it with the handle of the scalpel, and the sheath of the vessels comes clearly into view. If the internal cutaneous nerve be seen it should be drawn aside, but its division is a matter of small importance; the internal saphenous nerve lies some distance to the outer side of the artery. The sheath must be cautiously opened, a small hole being made in it as in the diagram (Fig. 500). It must be remembered that after the fascial sheath common to the artery and

Fig. 500.—Diagram of the Left Femoral Artery. *s*, sartorius; *f*, femoral sheath; *a*, artery.

vein has been opened, there is still the proper sheath of the artery to be divided before the ligature can be safely passed. The vein lies beneath the artery, and consequently the needle may be passed from the inner or outer side indifferently; it should be passed unarmed, and then be threaded and withdrawn. Usually, no nerve is seen during the operation, but the internal saphenous occasionally comes into view, and must be avoided. After the operation a drainage-tube should be inserted in such a way that its end shall lie beneath the sartorius, and the wound is closed with sutures. The limb is then semiflexed, somewhat raised, and laid on its outer side and wrapped in soft flannel or cotton wool. The severe pain which is usually complained of about the knee after the operation may be relieved by a full dose of opium.

In this operation there are several points of considerable importance that require special attention: 1. The incision should be made directly in the guiding line of the artery. 2. In cutting down upon the artery, the saphenous vein should be avoided, by taking care not to make the incision too far inwards. Any parallel venous branch that may be met with must be drawn on one side. 3. After the sheath has been opened, it will sometimes be found that a rather large muscular branch is given off from the artery at about the part where it was intended to ligature it; if so, this must be carefully avoided, as well as any small veins that cross the main trunk in this situation. 4. The ligature should not be applied less than four inches below Poupart's ligament, so that sufficient space may intervene between the origin of the deep femoral, which is usually from one or two inches below the ligament, and the point deligated, to admit of the formation of a proper coagulum in the vessel. It has, however, happened that the ligature has been placed within three-quarters of an inch of the origin of the deep femoral, without any injurious consequences resulting. 5. The greatest care must be taken not to wound the femoral vein, which lies behind the artery in the situation in which a ligature is usually applied. If the vessel is tied a little higher than usual, the vein will be towards the inner side, and then the needle must be passed from within outwards. Wounding the vein is best avoided by properly cleaning the artery; the white external coat must be thoroughly exposed, and while the needle is being passed the sheath should be put thoroughly on the stretch, the

Surgeon holding the edge of the opening on the side from which he is passing the needle, while the assistant catches the opposite side in a pair of forceps and draws gently upon it. In passing the needle, its end should be kept very close to the artery, and made to circle round it. The vein is generally perforated by dipping the needle too deeply and losing the contact between it and the artery. When the needle is brought up on the outer side of the artery, a small portion of the sheath is sometimes pushed up by it; this must be torn by pinching it with the forceps, when the needle may be carried round the vessel.

*Collateral Circulation.*—After ligature of the common femoral this is carried on by the anastomoses of internal pudic with external pudic branches of femoral; gluteal and circumflex iliac with external circumflex; obturator with internal circumflex; sciatic with internal circumflex and perforating branches of the profunda. After ligature of the superficial femoral the collateral circulation is through the anastomoses of the external circumflex with the articular branches of the popliteal, and by a series of communications between sciatic, internal circumflex, perforating arteries, and articular branches of popliteal. The *comes nervi ischiadici* may take an important share in the collateral supply.

*Results.*—Ligature of the femoral artery for popliteal aneurism is an operation that has so frequently been performed, that Surgeons seldom think of recording cases of this description, unless they present unusual complications or sequelæ; hence, but little importance can be attached to any statistical deductions from reported cases as to the fatality of this operation, although they may serve as a rough estimate of the proportion maintained between the different accidents, such as hæmorrhage, gangrene, &c., that follow it. That the ligature of the femoral artery is attended with more success than that of any of the other large trunks, can admit of no doubt. This is not only in accordance with the general experience of Surgeons, but is confirmed by the statistics of published cases, even without making allowance for the probability of more of the unsuccessful than of the successful having been recorded. Thus of 110 cases, collected by Crisp, in which the femoral artery had been ligatured for popliteal aneurism, only twelve are reported to have died: amongst these, four deaths were caused by secondary hæmorrhage, three by gangrene, and the others by phlebitis, tetanus, chest disease, &c. Higher rates of mortality are, however, given by other authors: thus, Norris states that nearly one in four die after this operation; Hutchinson finds that of thirty-three cases operated on in London, ten were fatal, five deaths resulting from gangrene. Holmes's statistics, which are extremely valuable as being collected directly from hospitals and not from published cases, show very favourable results. Of eighty-seven cases in which the operation was performed for femoral or popliteal aneurism, thirteen died, and in three the operation failed to cure the disease. Gangrene occurred twice, and suppuration of the sac not once. Of the deaths, one was from small-pox, two from wound of the vein and phlebitis, three from pyæmia, one from gangrene and amputation, one from disease of the kidneys, and the rest from various other causes. Barwell has collected also from hospital reports 67 cases occurring in the ten years 1870 to 1879 inclusive. Of these ten died. Most of the deaths occurred, however, in the first half of this period, in which 32 cases were operated on, with 7 deaths and 2 amputations: while in the

second half, out of 35 cases there were 3 deaths and no amputations. Barwell has also contrasted the results with reference to the various materials used as ligatures. He finds that in 14 cases silk was used; of these 3 died, 1 of rupture of an aneurism at the site of ligature, 1 of secondary hæmorrhage, and 1 of pyæmia, and in 1 case the aneurism relapsed. In 27 cases catgut was used; of these 6 died and 3 relapsed. Of the deaths, 1 arose from causes unconnected with the operation, 2 were due to secondary hæmorrhage, and 2 occurred after retying for relapse or aneurism at the site of ligature. In 4 cases the ox-aorta ligature was used successfully. The catgut used some years ago was somewhat uncertain in its quality, and in one of the cases in which secondary hæmorrhage occurred, it was applied without antiseptic precautions, and consequently differed but little from the old silk ligature in its properties. It remains to be determined what form of ligature gives the best results—whether catgut prepared according to the later methods (see Vol. I., p. 446), carbolized silk, or the ox-aorta, applied in such a way as not to divide the inner and middle coats. There is little doubt that the low death-rate of the later period is due to improvement in the ligature and in the after-treatment of the wound, and there is every reason to hope that it will at least be maintained, and probably further reduced.

**Accidents.—Wound of the Femoral Vein** is without doubt the most serious accident that can happen in the operation for ligature of the superficial femoral artery, and is one of which there is especial risk when it is undertaken for aneurism, as the sheath of the vessels is often thickened and indurated by chronic inflammation extending upwards from the sac. The accident is best avoided by thoroughly exposing the external coat of the artery before attempting to use the needle, which, as already recommended, should be passed unarmed and without the employment of force. There are but few cases on record in which the patient has survived this accident, death usually resulting from septic phlebitis or from gangrene. The cause of the fatal result was first pointed out by Hadwen. He showed that in wound of the vein the vessel is transfixed by the needle, so that when the thread is tied a segment of the wall is included with the artery in the noose, a portion of the ligature thus lying actually in the lumen of the vein. Upon the foreign body the blood necessarily coagulates, and a clot forms, obliterating the vein above and below the injured spot. In former times, when silk ligatures were used, the ends of which hung out of the wound, the thread always became more or less impregnated with decomposing matter, and thus septic changes were set up in the clot, leading to spreading phlebitis, disintegration of the clot and fatal septic embolism. Even if the patient escapes this danger, the simultaneous obliteration of the artery and vein almost invariably so far impedes the circulation as to cause gangrene. Guided by this view, the treatment becomes obvious. It consists in removing the ligature at once, and thus converting the wound into a simple puncture of the vessel which readily heals. The Surgeon should, therefore, as soon as the accident is perceived, withdraw the ligature, and, opening the sheath about half-an-inch higher up, re-apply it to the artery there. The hæmorrhage from the punctured vein readily ceases on the application of a compress.

The occurrence of **Secondary Hæmorrhage** after ligature of the superficial femoral is a troublesome accident, and one in which the Surgeon, to use Fergusson's expression, "will most assuredly find himself in an eventful

dilemma ;" and in which it is necessary that his line of action should have been well considered beforehand, as he may not have much time to spare for reflection when the emergency occurs. In cases of this kind four lines of treatment present themselves, viz. : ligature of the vessel at a higher point ; deligation of the bleeding artery in the wound ; the employment of pressure ; and amputation of the limb.

*Ligature* of the superficial femoral at a higher point, or, if the artery have been tied too high for this, deligation of the common femoral or of the external iliac, presents itself as a probable means of arresting the hæmorrhage. Such an operation, however, is fraught with danger, and has, I believe, almost invariably been followed by gangrene. It might at first be supposed that the limb would not be placed in a worse situation after the ligature of the external iliac, whether the superficial femoral had been previously tied or not ; the anastomosing channels remaining the same in either case. But in reality it is not so ; for, although the blood might find its way through the epigastric, the circumflex iliac, the gluteal, and sciatic arteries, into the common femoral and the branches of the profunda, yet from this point the difficulty of its transmission through the limb would be materially increased. If the superficial femoral be open, it serves as a direct and easy channel for the conveyance, to the vessels of the leg and foot, of the blood brought by the anastomoses. But when the superficial femoral is tied, this blood must find its way through a second chain of anastomosing vessels,—those intervening between the branches of the deep femoral and the articular arteries of the knee ; and here the real difficulty would arise, its impulse not being sufficient to overcome the obstruction to its passage through these small channels, which might not improbably be still further obstructed by the pressure of the aneurism. Should the anastomosing circulation be sufficiently free to maintain the vitality of the limb, it is not improbable that the recurrent blood would escape from the distal side of the ligature, and thus keep up the hæmorrhage exactly as in case of wound. Of 14 cases collected by Harrison Cripps in which the external iliac was ligatured for secondary hæmorrhage from the superficial femoral only 2 recovered—one after amputation for resulting gangrene and the other after recurrent hæmorrhage had been treated by pressure.

There is indeed no reason for departing from the general rule to *cut down upon the bleeding part and apply a ligature to it*. That such an operation is surrounded with difficulties cannot be doubted ; yet none would present themselves that care and skill might not overcome. The Surgeon would certainly have to cut into a part infiltrated with blood, in which the different tissues could not readily be distinguished, and the vessel when reached would be found to be inflamed and softened ; yet, by free dissection above and below the wound, a portion of it might at last be exposed, where its coats would hold a ligature.

Should the Surgeon fail in his attempts to secure the bleeding point an endeavour should be made to arrest the bleeding by *pressure*. This has also been successfully adopted as the first treatment in some instances : thus of 15 cases collected by Cripps of secondary hæmorrhage from the femoral treated by pressure 12 recovered.

In employing this method a graduated compress of lint or compressed sponge should be applied to the wound ; the whole limb is then bandaged from the toes to the groin, a second compress being placed over Poupart's ligament and

the graduated compress on the wound being fixed by a tourniquet for some hours. Cripps recommends that if the bleeding recur, the whole must be re-applied. *Amputation* may be required as a last resource, and should be performed when the other methods have failed or when gangrene has supervened.

**Gangrene of the Limb** is perhaps the most frequent source of danger after ligation of the femoral artery for popliteal aneurism. It seldom occurs unless the tumour be of considerable magnitude, have become diffused, or otherwise interfere seriously with the circulation through the limb. I have, however, seen it follow the operation when the popliteal aneurism was not larger than an orange; but, in this case, there was much œdema and congestion of the limb before the operation; and, on examination afterwards, it was found that the popliteal vein had been obliterated by the pressure of the tumour. The gangrene may, in some cases, be prevented by the treatment that has been pointed out at p. 911 *et seq.*, Vol. I. When it has fairly declared itself, there is necessarily no resource left but amputation, and this operation is sufficiently successful; for I find that of fourteen cases in which it was done, there were ten recoveries, and but four deaths.

The **Return of Pulsation in the Sac** after the operation for popliteal aneurism is by no means of frequent occurrence; yet it has been met with in some instances, and **Secondary Aneurism** also has been found in this situation. The treatment of this condition has already been considered at p. 128.

**Ligation of the Femoral Artery in the Middle of the Thigh (Hunter's Canal).**—The point at which Hunter tied

Fig. 501.—Diagram of Ligation of the Left Femoral Artery in Hunter's canal. *s*, sartorius drawn inwards; *f*, fascia closing the canal, opened freely; *a*, the artery, with a small opening in its sheath for the passage of the needle; *an*, long saphenous nerve.

the artery in his earlier cases was situated midway between the groin and the knee. At this point the artery lies in the angle formed by the vastus internus on the outer side, and the tendons of the adductor longus and adductor magnus behind. It is covered by a distinct fascia passing between these structures, forming with them the space known as Hunter's canal. The vein at this point lies to the outer side of the artery, and the long saphenous nerve enters the canal external to the vessels and crosses them superficially. The sartorius muscle covers the fascia closing in the canal. To tie the artery in this situation, the limb is placed in the same position as for the operation in Scarpa's triangle, and the same guiding-line must be taken to find the course of the artery; the incision, however, must not be made in this line, but one finger's breadth internal to and parallel to it; otherwise the edge of the sartorius is easily missed. The incision must be from three to four inches in length, and its middle point must correspond to the middle of the thigh. The fascia lata is

exposed, and opened, and the sartorius then comes into view. Its outer edge being found, it is pushed inwards, and held on one side with a copper spatula. The fascia closing the canal is then seen, and must be opened for about an inch and a half, thus exposing the sheath of the vessels (Fig. 501). If the saphenous nerve is seen, it must be drawn to one side with a blunt hook. The vein does not as a rule come into view, for as the limb is lying on its outer side it is beneath the artery. The sheath of the artery is carefully opened and the

needle passed from the outer side, the same precautions being taken as in the higher operation to avoid wounding the vein. The ligature should, if possible, be placed about one inch above the origin of the anastomotic branch. The errors that have to be guarded against in this operation, are, first, operating too low down. It must be remembered that Hunter's canal is situated midway between the groin and the knee. Secondly, if the wound be made too far out—in the guiding-line of the artery instead of a finger's breadth internal to it—the outer border of the sartorius may be missed, and the vastus internus exposed instead. At this point there is usually an interval in the muscular fibres of the muscle that may be mistaken for the edge of the sartorius. The error is, as a rule, easily recognized by observing the direction of the muscular fibres, those of the vastus internus being directed downwards and outwards, while those of the sartorius are nearly vertical, slanting a little inwards. It is important that the fascia closing the canal should be opened freely, otherwise should pus form it may burrow along the artery into the ham.

The **External Iliac Artery** may require to be tied in cases of popliteal aneurism, when the superficial and common femorals are so diseased as not to admit ligature. This occurred once to me. A gentleman who had lost the left foot and leg from spontaneous gangrene, two years afterwards became the subject of a large popliteal aneurism in the other leg. As compression failed, it was decided to tie the superficial femoral. On cutting down on the vessel the coats were found so diseased, the artery itself being dilated and slightly aneurismal, that the operation was abandoned; and, as the common femoral felt dilated and almost incompressible from calcification of its coats, it was decided to tie the external iliac. This I did with the able assistance of Sir W. Fergusson, at a rather high point, the vessel being somewhat dilated and calcified lower down. Pulsation recurred in the tumour a few hours after the operation, the collateral circulation being very free, and the patient died of secondary hæmorrhage on the fifteenth day.

**Double Popliteal Aneurism.**—In cases of this kind the artery has occasionally been ligatured with advantage on both sides, either simultaneously, or, with more safety, consecutively. But these cases appear to me especially adapted for the employment of pressure, so as to avoid that disturbance of the balance of the circulation which is certain to ensue when one vessel is ligatured, and which may act injuriously upon the opposite aneurism. When the popliteal aneurism is conjoined with a similar disease in the groin, ligature of the external iliac is the proper course to pursue, and will effect a cure of both.

**Diffused Popliteal Aneurism.**—When a *circumscribed* popliteal aneurism suddenly becomes *diffused*, the patient is seized with faintness or sickness, with pain, numbness, and a hot trickling sensation in the limb, the temperature of which falls at the same time that its bulk increases, whilst the integument assumes a white, shining, mottled appearance with more or less purplish discoloration. After a time as the tension increases inflammation is set up, and the skin becomes red, hot, and cedematous, and the whole swelling may resemble in appearance a large abscess. Diffusion usually occurs after a circumscribed aneurism has existed in the ham for some weeks or months, and after some sudden exertion. In some cases, however, the disease appears to have been diffused from the very first, the coats having given way, and extravasation having taken place into the areolar tissue of the

limb, without previous consolidation of the parts around the artery, or any attempt at the formation of a sac. In these cases the extravasation into the limb may either be conjoined with much œdema; or it may be confined to the areolar tissue of the ham, and to the upper and back part of the leg, or may extend downwards under the muscles of the calf. When the patient comes under the observation of the Surgeon, the tumour is found to be solid, elastic, and irregular, often without pulsation or bruit; the limb œdematous, cold, and congested. The diagnosis of this form of aneurism is often extremely difficult, and there is great danger of confounding it with simple extravasation into the calf, with abscess, or, possibly, with malignant tumour of the leg.

**Treatment.**—The danger attending on popliteal aneurism is greatly increased by its becoming diffused. In these circumstances the ligature of the artery usually affords but a slender prospect of success, the collateral vessels being so compressed and choked by the pressure of the effused blood as not to admit of the circulation being carried on through them; hence the Surgeon has but two courses open to him, to lay the sac open, turn out the clots, and tie the vessel above and below the opening, or to amputate the limb.

The **Old Operation for Diffused Popliteal Aneurism** is undoubtedly a most difficult proceeding, owing to the depth at which the vessel lies and the position of the popliteal vein and the internal popliteal nerve superficial to the sac. In former times it was almost invariably followed by profuse and prolonged suppuration, and if the patient escaped the danger of secondary hæmorrhage, septicæmia and pyæmia, he recovered with a stiffened limb, often flexed to a considerable angle by the contraction of the scar in the ham. The operation was, therefore, at one time abandoned in favour of amputation. In the present day, with the help of Esmarch's bandage to render the limb bloodless, and antiseptic treatment, there is no reason why an attempt should not be made to turn out the clots and tie the vessel in every case in which gangrene has not actually set in, and in which the Hunterian operation is evidently inapplicable, but the Surgeon must be prepared to amputate immediately should he fail to secure the artery. In opening the sac the incision should be made in such a way as to avoid the vein. When the mouth of the sac is found, a full-sized bougie should be passed into it so as to distend the vessel, making it possible to clean it thoroughly before passing the needle.

**Amputation for Diffused Popliteal Aneurism** is the only resource should the Surgeon fail to accomplish the old operation, or should gangrene already have declared itself. It is often difficult to determine what treatment to adopt in these most anxious cases. There are, however, certain general considerations that may guide the Surgeon in his decision.

1. In some cases, the sac has either given way to a very limited extent; or else its walls, having become thin and expanded, are yielding rapidly under the pressure of the blood, becoming confused with the surrounding parts. Here we should ligature the artery without delay: for although it is but seldom that a limb can be saved when once the blood has become infiltrated into the general areolar tissue, yet it is possible that such a fortunate occurrence may happen.

2. In other instances the aneurism has not from the first been very distinctly circumscribed. It has followed the infliction of some mechanical injury, and in the course of a week or two has acquired a considerable size, without definite or distinct limitation, being solid or but little compressible.

Such a case as this can scarcely be considered, strictly speaking, a diffused aneurism; but yet, if by *circumscribed* we mean that the blood is contained in a cyst with defined walls, it scarcely agrees with such a definition, the fluid blood being rather prevented from escaping widely by a temporary barrier of coagula entangled in the loose areolar tissue of the part, and the vessel being extensively ruptured or completely torn across. Here we are certainly justified in having recourse to compression or ligature, with a good prospect of success.

3. When the ham is occupied by a large rapidly increasing tumour, extending perhaps some way down the calf and up the thigh, and encroaching on the knee, the skin covering it being more or less discoloured, there being no pulsation perceptible in the tibial arteries, and the veins of the limb being full and even somewhat congested, the foot œdematous and several degrees cooler than the opposite limb, the difficulty of coming to a decision is considerable.

In such a case as this, I think that the existence or absence of distensible pulsation is a circumstance of very great importance, and may serve to guide the Surgeon. If there be distinct impulse of a distending character, which can be arrested by compression of the femoral artery, with some diminution of the size of the tumour, it is evident that blood is being transmitted through the sac, and that this contains some fluid blood. In these circumstances it will, when the artery is tied, subside to a considerable extent, thus allowing more space for the conveyance of the collateral circulation; and it would be but right to give the patient the chance by ligaturing the vessel.

If, however, the tumour have, from the very first time when it attracted the patient's notice, been more or less solid and incompressible; and, though it may at an early period have pulsated, if this pulsation have suddenly ceased, the aneurism at the same time having undergone rapid and great increase of bulk with much tension and lividity of the integuments, œdema and coldness of the limb, with a tendency perhaps to vesication and sloughing of the skin covering the tumour, an attempt may be made to perform the old operation, everything being prepared for immediate amputation in case of failure.

It must, however, be borne in mind that the aneurism may become diffused, and extensively so, without any very great change in the shape and size of the limb. It is only when the sac ruptures in such a position that the blood escapes into the general areolar tissue of the limb or under the skin, that much tension of the integuments and increase in the bulk of the part take place.

4. When a rupture occurs in a part of the sac that is more deeply seated, the blood is extravasated underneath the deep fascia of the leg, and is bound down by this; and disorganization of the interior of the limb may be the result, without much change in its bulk or in the colour of the integuments, but with excessive deeply seated pain. There must always be considerable risk, in such a case as this, of confounding the arterial disease with a solid tumour; and the diagnosis can be made only by reference to the early history of the case, and more particularly to the existence or absence of pulsation at this period. Indeed, the existence or absence of pulsation in these cases is of the utmost importance in reference to the question of treatment. The pulsation may have ceased in a case of diffused popliteal aneurism, in consequence of the blood that has been extravasated being so confined

and bound down by the fascia and muscles under which it is effused, that it compresses the mouth of the artery leading into the sac, to such an extent as to arrest the passage of blood through it, either wholly or so that it enters in a feeble stream of insufficient force to communicate an impulse to the fluid that has been extravasated into the limb. This pressure may, as in the case of which an illustration has been given (Fig. 450), be confined to the deep parts of the limb, and not give rise to much, if any, general tension of it, the blood being confined below the deep fascia, where it communicates the sensation of a hard, solid elastic tumour devoid of pulsation. Attention should consequently not be too exclusively directed to the state of general tension of the surface of a limb, as this is by no means necessarily an indication of the state of the parts beneath; but the Surgeon should look rather to the presence or absence of pulsation. If pulsation still exist, the blood continues to find its way into the sac, and most probably through it, the tension of the parts not having yet reached its maximum. If there be no pulsation, he may be sure that the entrance of blood into the diffused aneurism has ceased in consequence of compression exercised on the mouth of the artery leading to it, by the tense condition of the surrounding tissues reacting on the mass of blood effused beneath them. In such a state of things as this, the vitality of the lower part of the limb can be maintained only by the blood that may find its way through the anastomosing channels; and this may be sufficient for the purpose if the tension of the limb be not general, the extravasation being confined below the deep fascia. If surgical interference be delayed in such a case as this, the deep fascia will soon give way by over-distension and rupture, and the blood will be infiltrated into the general areolar tissue of the limb; and then, by compressing those collateral branches that have hitherto maintained a feeble circulation in it, will infallibly occasion gangrene. If, on the other hand, recourse be had to ligature of the main artery, the anastomosing circulation, which may have been barely sufficient to keep up a feeble vitality in the leg and foot, will be so much interfered with that gangrene of the limb inevitably ensues. In these cases an attempt may be made to save the limb by laying open the sac and ligaturing above and below its mouth. Should it be impossible to accomplish this the only resource left is to amputate at once.

5. When gangrene threatens, the leg and foot having become cold, the skin being either pale, tallowy, and mottled, or discoloured, of a purplish hue, with perhaps vesications and much oedema, whether the ligature have been previously applied to the femoral artery or not, or whatever the condition of the aneurism may be, whether circumscribed or diffused, the patient will stand a better chance of ultimate recovery by having the limb removed at once above the knee. If the amputation be the primary operation, it should be done at the lower third of the thigh, provided the extravasation be confined to below the knee; or higher up, if the effused blood have extended above this joint. If the femoral artery have already been ligatured, the thigh should be amputated on a level with the ligature, lest sloughing of the flaps occur.

ANEURISMS OF THE TIBIAL ARTERIES are extremely rare, except as the result of wound, yet they are occasionally met with; and in the museum of St. George's Hospital there is a preparation of a small aneurism of the posterior tibial. I have seen only one case during life, that of a man suffering from cardiac and renal disease, admitted into University College

Hospital under my care for an aneurism of the anterior tibial at the lower part of the upper third of the right leg. The signs were well marked—pulsation forcible and excentric, bruit loud. Compression was used without avail; and as he was anasarctous, no other surgical treatment could be adopted. He left the hospital uncured.

The popliteal and tibial arteries sometimes require ligature for injury, but very rarely for disease. The operation may be briefly described here.

**Ligature of the Popliteal Artery.**—The popliteal artery may be tied at any part of its course. In the *lower two-thirds* it can be reached only by an incision in the line of the vessel. The external saphenous vein will be found in the subcutaneous tissue, and must be avoided. After dividing the deep fascia the internal popliteal nerve must be found and drawn to the outer side. The vein then comes into view and must be drawn out of the way, when the artery will be exposed lying deeply on the posterior ligament of the knee-joint. This operation is never undertaken except for a wound, and consequently must always be more or less of an informal character. In its *upper third* the vessel is reached most easily from the inner side. The guiding line for the incision is the posterior border of the tendon of the adductor magnus. The knee is flexed and the limb placed on its outer side, and an incision is made from three to four inches in length parallel to the tendon of the adductor magnus and immediately behind it. Its upper extremity should correspond to the junction of the lower and middle thirds of the thigh. The skin and superficial fascia are divided, avoiding the long saphenous nerve if possible, and the deep fascia opened. The edge of the tendon of the adductor magnus, which forms the first rallying point in the operation, is then sought for. Some branches of the anastomotica magna are divided at this stage of the operation and require ligature. When the adductor tendon is found, the sartorius and gracilis and inner hamstring muscles are pushed backwards with the finger and held with a copper spatula. Care must be taken not to pass the spatula between the bone and the artery, which is surrounded in this situation by a considerable amount of loose fat. This fat being torn through, the artery is exposed without much difficulty. The vein and the internal popliteal nerve lie to the outer side and are not seen. The ligature should not be applied too near the superior articular branches.

**Ligature of the Posterior Tibial Artery.**—The line of the posterior tibial artery is from a point about one inch below the knee, and equidistant from the two sides of the limb, to a point one finger's breadth behind the inner malleolus. The vessel may be tied at any part of its course, but the procedure has rarely been undertaken as a formal operation except about the middle of the calf or behind the inner malleolus.

In the *middle of the leg* the posterior tibial artery should be tied only for a wound, and in such circumstances, as a rule, no regular operation can be performed; but an incision of sufficient length, taking the wound for its centre, should be made through the gastrocnemius and soleus parallel to their fibres, when, after these have been cut through, the deep fascia will be exposed. This must next be opened, when the artery will be found accompanied by its veins, and having the nerve to the outer side. From the depth at which the vessel is situated, and the free incisions that it is necessary to make through muscular parts, it is extremely difficult to apply the ligature in this situation.

The later steps of the operation may be much facilitated by flexing the leg on the thigh, and extending the foot, so as to relax the muscles.

The regular operation as performed on the dead body is rarely required on the living. It is thus carried out. The limb is flexed and laid on its outer side. An incision is made four inches in length parallel to the inner border of the tibia and about one inch behind it. The internal saphenous vein must be avoided if its situation can be ascertained. On dividing the deep fascia the edge of the gastrocnemius, if it has not fallen away to the outer side in the position of the leg, will come into view and is to be pushed to one side,

exposing the surface of the soleus. This is next to be divided, the edge of the knife being now turned towards the posterior surface of the tibia. After cutting through about half an inch of muscular tissue a tendinous layer is exposed. This is the tendon of the deep surface of the soleus, and forms the first important rallying point in the operation. The tendon having been exposed in the whole length of the wound, it is picked up in the middle with a pair of forceps and carefully opened. The operator must now look to see if muscular fibres arise from its under surface. As a rule, no fibres arise from the internal half inch of the deep surface of the tendon, and if the incision through it be made at this point, the space between the deep and superficial muscles in which the artery lies is immediately opened. If the incision be more external, the fibres arising from the deep surface of the tendon must be divided before the proper space is opened. As soon as this is reached, the outer part of the soleus and the gastrocnemius must be drawn well outwards with a copper spatula, and the artery comes into view with a vein on each side, and the nerve most commonly to the outer side. The vessels are covered by the fascia which separates the superficial and deep muscles. Care must be

taken in dividing the soleus not to wound the latter fascia, as, should this happen, the artery is easily lifted with the superficial muscles. The needle should be passed from the side on which the nerve lies.

The *posterior tibial artery behind the malleolus* is reached by making a semi-lunar incision about two inches in length, curving round the posterior and lower part of the malleolus, and one finger's breadth behind it. After dividing the skin and fat, the internal annular ligament comes into view. If the guiding line have been accurately adhered to, the artery will appear immediately the annular ligament is divided. It has a thick-walled vein on either side of it, which may be mistaken for the artery in a bloodless limb, unless it be carefully examined. The nerve lies behind and external to the artery, and the needle must be passed from behind. The most common error in tying this artery arises from keeping to the convex instead of to the concave side of the wound while deepening the incision. The deep parts of the incision thus gradually approach the malleolus, and the tendons are reached instead of the artery. The tendon of the tibialis posticus is that exposed, as it is most superficial. The artery must then be looked for behind this, and *immediately beneath the annular ligament*. If the dissection be carried on past the sheath of the tibialis posticus till the flexor longus digitorum comes into view, it will pass beneath the artery, which is usually then held out of the way in the

posterior blunt hook, and is thus missed. The flexor longus hallucis lies so far behind the artery that it is scarcely possible to expose it.

The **Anterior Tibial Artery** may be tied in several situations ; but, like the posterior tibial, it should not be ligatured in the upper or middle parts of the leg, except for injury. The difficulties of the operation are lessened as the ankle, where the artery becomes superficial, is approached. The line of the anterior tibial artery is from the inner side of the head of the fibula to a point exactly midway between the two malleoli ; and the course of the dorsal artery of the foot is from this point to the cleft between the first two toes.

In the upper third of the leg the artery lies deeply between the tibialis anticus and extensor longus digitorum, surrounded by veins and having its nerve to the outer side. If it ever be found necessary to tie it in this situation, an incision should be made in the guiding line of the artery, from four to five inches in length. The deep fascia must be opened, and, if necessary, notched transversely. In the upper fourth of the limb the tibialis anticus arises from the fascia, which adds somewhat to the difficulty of finding the interval between the muscles. The first intermuscular space to the outside of the tibia is the one to be sought for. When it is found the ankle must be flexed to relax the muscles, which are then held apart with copper spatulæ. The artery may then be cleaned with a director, and the needle passed obliquely beneath it. In operating high up in the limb it is possible to slip into the space between the peronei and the extensor longus digitorum. This error is at once recognized by finding a distinct fibrous intermuscular septum, no such structure existing between the tibialis anticus and the extensor digitorum.

In the middle and lower thirds of the leg the artery will be found between the tibialis anticus and the extensor proprius hallucis ; the latter muscle does not, however, reach the surface above the middle of the leg. The right space is found by keeping accurately to the guiding line of the artery, and, after the fascia is opened, taking the outer border of the tibialis anticus as the guide. The edge of the extensor longus digitorum is recognized by its rounded tendon, reaching considerably above the middle of the leg, with fleshy fibres joining it on the outer side.

The **Dorsal Artery of the Foot** runs from a point midway between the two malleoli to the base of the space between the first and second metatarsal bones, and may be felt pulsating in this line. It lies external to the tendon of the extensor proprius hallucis, and is crossed near its lower end by the internal belly and tendon of the extensor brevis digitorum. It is sometimes absent, and not unfrequently lies external to the line just mentioned. It is reached by an incision in the line of the artery, one inch and a half in length, the lower end of which corresponds to the base of the space between the first two metatarsal bones. The superficial and deep fascia being divided, the artery may immediately come into view. If it does not, the inner belly and tendon of the extensor brevis must be sought for, and its inner border followed till the long extensor is reached. If the artery is not seen passing beneath the tendon of the short extensor, that muscle must be forcibly pulled outwards and the vessel sought for beneath it. If it does not then come into view, it is probably absent. The termination of the anterior tibial nerve accompanies the artery when it is in its normal situation, and lies usually to the outer side.

The **Peroneal Artery** has been tied in rare cases for wound in the middle of the leg. It is found by making an incision about three inches in length on the external border of the fibula, which is the first rallying point in the operation. A thin tendinous layer, forming part of the origin of the soleus, and sometimes a few fleshy fibres, are found attached to the bone. On dividing these, the flexor longus hallucis comes into view. This is cut carefully away from the posterior surface of the bone, and at its inner edge a tube of fascia is found, in which the artery lies between the flexor longus hallucis and tibialis posticus. This must be opened, and the venæ comites separated with a director, after which the needle is easily passed.

## DISEASES OF THE ORGANS OF SUPPORT AND MOTION.

### CHAPTER XLVI.

#### INFLAMMATION OF BONE AND ITS EFFECTS.

##### GENERAL PATHOLOGY OF INFLAMMATORY AFFECTIONS OF BONE.

BEFORE considering the diseases of bone as they present themselves in practice, it will be convenient to describe the different effects of inflammation on the separate structures of which a bone is composed, viz., the periosteum, the medulla and the osseous tissue. The necessity for this arises from the fact that inflammatory affections are rarely limited to one of these structures. Thus inflammation commencing in the periosteum, if it last for any length of time, always produces more or less marked changes in the compact tissue beneath, and the cancellous tissue is never affected without the periosteum sooner or later taking part in the morbid process.

The process of inflammation in bone is essentially the same as in all other tissues—such modifications as exist being due solely to the structure of the affected part. In the Chapter on Inflammation it was pointed out that in the more acute or destructive processes of inflammation the inflamed tissue becomes infiltrated with new cells, before which the original structures disappear. In the soft parts of a bone, the medulla and periosteum, this takes place exactly as in other tissues, but in compact bone the process is restricted and delayed by the density of the structure. The new tissue undergoes the same changes in bone as elsewhere: it may soften and break down into pus, it may suffer from fatty degeneration and caseation, or it may develop, the product being as a rule osseous, instead of fibrous tissue, as in the soft parts. The chronic inflammatory processes which in the soft parts lead to fibroid induration or overgrowth of the connective tissue, when affecting a bone lead to the formation of new osseous tissue, but the process is essentially the same. As in other parts the inflammation may end in death of the affected tissue. Acute infective inflammations are also met with, and the chronic processes associated with the presence of tubercle are common. All these inflammations are identical in character with those already described as affecting the soft parts, such differences in detail as exist being due solely to the physical peculiarities of the tissue implicated.

**INFLAMMATORY PROCESSES IN THE PERIOSTEUM.**—The periosteum is composed of two layers, the more superficial of which consists chiefly of white fibrous tissue; the deeper contains a large proportion of yellow elastic tissue. Forming part of the deep layer in immediate contact with the bone is a stratum which contains numerous cells. In growing bone these have the

ordinary appearance of the cells always found immediately preceding the formation of new bone, the so-called osteoblasts; they are granular and somewhat angular in outline. In adult bone these are represented by flattened cells, but they readily resume the form of osteoblasts under slight degrees of stimulation. The periosteum is extremely vascular, the vessels breaking up in it and entering the Haversian canals of the bone beneath, and numerous nerves may be traced in its structure. The effects of this structure in modifying the process of inflammation are obvious. The extreme vascularity of the membrane favours exudation, and the inflammatory products accumulate most abundantly in the deeper layers, and between them and the bone, beneath the denser fibrous layer. They penetrate also along the vessels into the Haversian canals. Owing to the abundant nervous supply and to the tension caused by the unyielding nature of the superficial layers of the periosteum, inflammatory exudation is often accompanied by very severe pain. Should the inflammation terminate in suppuration the vessels passing from the periosteum to the bone are destroyed, and death of a portion of the compact tissue may result. This is, however, by no means a necessary consequence, especially if the periosteum be separated only to a small extent, as the blood supply from the medulla is sufficient to maintain the vitality of the denuded bone. Sloughing of the periosteum as a result of inflammation is a somewhat rare occurrence owing to the abundant vascularity of that structure. Lastly, new bone is formed with great readiness in all chronic inflammatory processes in the periosteum, the mode in which it is developed being the same as in physiological growth, though wanting in regularity. The following are the names given to the various inflammatory processes occurring in the periosteum:—(1.) Simple Acute Periostitis; (2.) Suppurative Periostitis, *a.* Simple and Localized, *b.* Infective and Diffuse; (3.) Chronic Periostitis, *a.* Osteoplastic, *b.* Gummatous, *c.* Tuberculous.

**1. Simple Acute Periostitis.**—This is most commonly the result of injury. The membrane is redder and thicker than natural. It separates easily, and as it is stripped off fine threads are seen passing from it into the bone; these are the vessels which are loosened by the exudation into the Haversian canals, and consequently draw out more readily. On section the swollen membrane presents a somewhat gelatinous appearance, due to the infiltration of its structure with the inflammatory exudation; this is most marked in the deeper layers next the bone. Microscopic examination shows only the ordinary appearances of inflammation—dilatation of the vessels and infiltration of the fibrous tissue, especially its deeper layers with small round cells. Simple acute periostitis may end in resolution with a perfect return to the normal condition, or it may pass on to suppuration, but more commonly it becomes chronic and assumes the osteoplastic form.

**Suppurative Periostitis, (a) Simple Acute Periostitis,** resulting from injury occasionally terminates in suppuration. The pus forms between the membrane and the bone, and slowly perforates the fibrous layer. It shows but little tendency to extend beneath the periosteum or to separate it widely from the bone. It may be followed by death of the exposed portion of the compact tissue, but, as before stated, this is by no means necessary.

**(b) Infective Inflammation of the Periosteum** is a much more serious affection. It occurs chiefly, if not exclusively, in young subjects. It terminates very early in suppuration and the pus diffuses itself widely, stripping

the periosteum from the bone, sometimes throughout the whole extent of the diaphysis. When it reaches the epiphyses the suppuration extends in the growing tissue between them and the shaft, and thus in extreme cases the whole diaphysis may lie loose in the cavity of a large abscess enclosed within the fibrous layer of the periosteum; finally, this is perforated, and the pus diffuses itself amongst the surrounding tissues. In spite of the acuteness of the process, the periosteum very rarely sloughs, and if exit be given to the pus the intensity of the inflammation subsides and the periostitis assumes the osteoplastic form, new bone being abundantly deposited beneath it. Infective periostitis almost invariably leads to death of a considerable portion of the bone which has been laid bare by the separation of the membranè, but the extent that perishes does not necessarily correspond to that separated from its periosteum.

**Osteoplastic Periostitis.**—This is essentially a chronic process. It occurs as a consequence of the slighter forms of irritation, or as a sequel of acute inflammation. It is very frequently met with also as an accompaniment of more deeply seated inflammatory mischief, as of the medulla or cancellous tissue, and in the neighbourhood of diseased joints. In young subjects it results from very slight sources of irritation, being then merely an exaggeration of the normal process of growth. In osteoplastic periostitis the membrane is thickened and more vascular than natural. It separates with some ease, and its under surface often feels gritty from small fragments of new bone that have come away with it. Beneath it and adherent to the compact tissue is the new bone formed as the result of the process. This may be arranged in smooth layers, parallel to the surface of the bone, in nodules or in pointed processes. When the nodulated or spiculated masses reach any considerable size they are frequently termed *osteophytes*. The new bone formed in the early stages of osteoplastic periostitis is soft and spongy, being traversed by large canals containing vessels surrounded by large cells. These canals are set at right angles to the surface of the bone. As recovery takes place the new bone is partly absorbed, the irregular nodular or spiculated masses are smoothed down and the remainder gradually increases in density, till it becomes indistinguishable from the compact bone beneath.

Microscopic examination of the parts involved in osteoplastic periostitis shows that the swollen membrane is infiltrated with small round cells, proportional in number to the acuteness of the process. In the deeper layers in contact with the newly-forming bone, the cells assume the characteristic angular shape and granular appearance of osteoblasts. There seems to be a direct transition from the granulation cells infiltrating the inflamed membrane to the osteoblasts, and it has therefore been supposed that they are developed from migrating cells, but, as in the case of productive inflammatory processes elsewhere, it seems probable that the original cells of the deeper layer of the periosteum are concerned in the formation of the new tissue after the acute stage has subsided. The new bone is formed subsequently in the same way as in normal ossification. A homogeneous ground-substance is developed between the osteoblasts which soon becomes indistinctly fibrillated and subsequently calcified. Some of the osteoblasts seem to disappear, while others remain, forming the bone-corpuscles. The development of the inflammatory new growth into bone commences at the points most distant from the vessels, and gradually encroaches on them till they come to lie in channels surrounded by

bone (Haversian canals). We have before seen that the same changes occur in the formation of callus in the repair of a fracture (Vol. I., p. 529), but in these circumstances cartilage occasionally appears before the development of bone. This is never met with in osteoplastic periostitis arising from other causes.

Billroth is of opinion that the new bone developed in osteoplastic periostitis is not always formed solely from the periosteum. That it is so in those cases in which the compact tissue beneath is dead is of course evident, but in other cases he believes that granulation tissue sprouting out of the openings of the Haversian canals takes part in the process. In the union of fractures the callus is partly formed from the injured soft parts superficial to the periosteum.

**Gummatous Periostitis** and the other varieties of inflammation of the periosteum resulting from syphilis have already been described. (Vol. I., p. 1157.)

Any localized chronic inflammatory swelling of the periosteum, whether simple or syphilitic, and whether accompanied by the formation of new bone or not, is commonly termed a *node*.

**Tuberculous Periostitis** is the result of the deposit of tubercle in the deeper layers of the membrane. In the majority of cases the tuberculous tissue undergoes caseation and a chronic abscess follows. The subjacent bone is usually sooner or later affected, so that it may often be impossible to determine the exact starting-point of the disease. Tuberculous periostitis is not common in the long bones of the limbs, but is met with in the ribs and in many cases of tubercle of the spine.

**INFLAMMATORY PROCESSES AFFECTING THE COMPACT TISSUE OF A BONE.**—The compact tissue of bone is composed of lamellæ arranged for the most part concentrically around the Haversian canals. Beneath the periosteum the lamellæ lose their concentric arrangement and lie parallel to the surface. Between the lamellæ lie the bone-corpuscles in the lacunæ and from these the fine canaliculi pass through the bony tissue. The Haversian canals are smallest near the surface, and gradually increase in size towards the deeper parts, so that the compact and the cancellous tissue gradually merge into each other without any sharp line of distinction between them. Each Haversian canal, except the very smallest, contains a small artery and vein, a flattened lymphatic vessel, and a pale nerve-fibre, surrounded by a small amount of delicate connective tissue containing branched cells. There is no reason to believe that the bone-corpuscles take any active part in the inflammatory processes in bone; all the changes observed proceed from the Haversian canals. The nature of the tissue in which the inflammation is taking place necessarily causes some modification in the phenomena. Exudation and migration of the corpuscles occur as in other structures, but the amount is somewhat limited by the unyielding nature of the surrounding tissue. The swelling of the delicate connective tissue in the Haversian canals will moreover tend to compress the vessels, and thus in acute inflammation of compact bone death of the affected part is very prone to occur from arrest of the flow of blood through it. Should this not happen, we see the same changes occurring as in other tissues; the new cells increase in number and the original tissue disappears before them. In bone this process is necessarily slow on account of the density of the structure, but ultimately a portion of the solid bone may be as completely

destroyed before the advancing cells as are the soft tissues in the formation of an abscess-cavity, or in ulceration of the skin. When recovery takes place the inflammatory products develop into bone instead of into fibrous tissue as in the soft parts. The compact tissue is also liable to chronic inflammatory affections of the same type as those leading to fibroid induration of the soft parts, but in bone the product of the process is new osseous tissue which develops in the Haversian canals, gradually narrowing them, and rendering the texture more dense than natural.

The inflammatory processes observed in compact bone are the following :— (1.) Rarefying or rarefactive osteitis; (2.) Osteoplastic or condensing osteitis; and (3.) Necrosis.

**Rarefying or Rarefactive Osteitis.**—This may occur as a secondary effect of inflammation commencing in the periosteum or in the medulla. It is observed also as the result of injury, as in a piece of bone denuded of its periosteum, or on each side of a fracture. In many cases its original cause is very obscure.

A portion of compact bone undergoing this change is in the earliest stages slightly redder than natural; the openings of the Haversian canals after a time become somewhat increased in size, and consequently a larger number are visible to the naked eye. As the process advances the Haversian canals increase at the expense of the bone surrounding them, and when they reach a sufficient size they can be seen to contain a small quantity of pink granulation tissue surrounding the vessel. If a portion of the bone at this stage be macerated it presents a porous spongy appearance, almost resembling cancellous tissue. If the process advances still further, as in the separation of a piece of dead bone, the neighbouring enlarged Haversian canals coalesce, the solid osseous tissue disappearing entirely, and a soft mass of granulation tissue fills the space once occupied by solid bone. The superficial layers of the granulation tissue may break down into pus under the same conditions that give rise to suppuration elsewhere, or, should the process cease, the new tissue develops into bone by the same process as in osteoplastic periostitis, the new osseous tissue being first formed in connexion with the old.

The rarefying osteitis may be limited to a small portion of the bone as in the separation of a sequestrum, or may be diffused over a wide area. In the latter case it is more chronic, and, although rendering the bone more porous than natural, rarely leads to its complete destruction for any great extent.

Microscopic examination of a piece of bone affected by rarefying osteitis shows the following appearances. In the earliest stage the vessels are distended with blood, and numerous cells, probably migrated leucocytes, are found in the delicate connective tissue contained in the Haversian canal. In a more advanced stage these cells are greatly increased in number, and the wall of the canal is seen to have been consumed away before them. The destruction of the osseous tissue takes place irregularly in excavated concentric hollows, first described by Howship, and consequently named "*Howship's lacunæ*" (Fig. 503, a). A large number of these will be found to be filled by cells of considerable size containing several nuclei, each cell corresponding to a lacuna. These multi-nucleated cells, which have received the name of *osteoclasts*, are found wherever bone is being destroyed, whether from inflammation or in a physiological process, as the development of the medullary canal. They lie

directly in contact with the bone, the rest of the space surrounding the vessels being filled with the ordinary small round cells of granulation tissue. Their mode of development and subsequent fate are uncertain. The osseous tissue which is yet undestroyed often presents no evident change. The bone-corpuscles certainly show no signs of taking any part in the process. Should they show any change, it is one of degeneration, not of proliferation. They may be unnaturally granular, and are sometimes represented merely by an oil-globule, or a mass of fat granules. They can in most cases be seen to be unaltered until the lacunæ in which they lie are opened by the advancing absorption of the osseous tissue, and after that their fate is unknown.

When the destructive process has advanced far enough to form a considerable space filled with granulation cells around the original vessel of the Haversian canal, new capillary loops are found penetrating amongst the new tissue, just as in the development of granulation tissue in a wound.

The destruction of bone by the pressure of a tumour or an aneurism, or its

Fig. 503.—Section of bone in which deposition by osteoblasts and absorption by osteoclasts are in progress (94 diams.). *a*, Osteoclasts and Howship's lacunæ; *b*, Osteoblasts.

infiltration by a malignant growth, is carried out by the same process as that just described, but in the former case, when the Haversian canals have become sufficiently enlarged, the special elements of the tumour penetrate into them, displacing the granulation tissue. The compact tissue may in like manner be invaded by the specific tissue of a syphilitic gumma.

Various terms are applied clinically to this rarefying osteitis under its different modifications. When the process is widely diffused, a large part of the shaft of a bone being rendered more porous than natural without complete destruction of the osseous tissue, it is sometimes termed *inflammatory osteoporosis*. When only a localised area is affected, as in the separation of dead from living bone, with complete destruction of the osseous tissue, and subsequent formation of pus from the granulation tissue replacing it, it is termed *simple ulceration of bone*. When it occurs as the result of the infiltration of the compact tissue by a subperiosteal gumma followed by softening and suppuration of the new growth, it is described as *syphilitic caries*.

**Osteoplastic Osteitis or Osteo-sclerosis.**—This is always an extremely

chronic process. It may occur as a sequence of diffuse rarefactive osteitis, or as the secondary result of some central mischief occurring in the cancellous tissue or medulla, or as a consequence of syphilis. Osteoplastic osteitis is characterized by a development of new bone in the connective tissue surrounding the vessels in the Haversian canals. The mode of formation of the osseous tissue is the same as in osteoplastic periostitis. As the result of the process the bone becomes greatly increased in density, frequently with complete obliteration of many of the Haversian canals. This may even go on to such an extent as to cut off the vascular supply from a portion of bone and thus cause its death. The bone may acquire the consistence of ivory. At the same time it may increase in thickness, partly from a simultaneous growth of bone from the periosteum, and partly apparently from interstitial growth in the bone itself. The new bone, though denser in structure, resembles healthy osseous tissue when examined by the microscope.

The two processes just described, osteoplastic and rarefactive osteitis, not unfrequently go on side by side, giving rise to the appearance known as **expansion of bone**. The compact tissue, when thus affected, becomes more spongy than natural, and the arrangement of its structure is often more or less completely altered. In normal compact tissue some of the superficial lamellæ lie parallel to the surface, but for the greater part they are arranged circularly around the Haversian canals; not unfrequently, however, we find in chronic osteitis that the compact structure undergoes a peculiar laminated expansion, so that a section of it presents throughout parallel layers, concentric with the medulla. The lamellæ are separated from each other by pink vascular tissue. This change is necessarily accompanied by considerable increase in size of the affected bone, which may extend throughout a great part of its length. Microscopic examination shows, in such a case as this, that the pink tissue between the bony laminae is composed chiefly of round cells, like those of ordinary granulation tissue, but on one side of the lamella the cells in contact with the osseous layer are assuming the form of osteoblasts, indicating that formation of bone is taking place; while, on the other, the surface of the lamella is irregular, presenting the hollows known as Howship's lacunæ, and in these are the large multi-nucleated cells, or osteoclasts, which are indicative of destruction of bone (Fig. 503). This process, when occurring as a pathological change, is usually regarded as inflammatory, but the close analogy between it and normal growth is evident. In the growing bone of a child the medullary canal is hollowed out by a process similar to that just described, and new bone is constantly deposited on the surface by the periosteum. In chronic osteitis with "expansion" of the bone, the chief difference is in the diffusion of the process throughout the compact tissue and its irregularity. If the source of irritation to which the expanding osteitis is due be removed, the destructive part of the change ceases and new bone is formed on both sides of the lamellæ, and thus, while the abnormal size is more or less completely retained, the structure becomes as dense as, or sometimes denser than, normal compact tissue.

In some few cases the appearances presented by the diseased bone are such as to suggest that the periosteum takes but little part in the process, but more commonly expansion of the compact tissue is associated with laminated deposits of new bone from the periosteum.

Expansion of bone by a tumour is a change of the same character, the destructive processes just described taking place in the parts pressed on by the

growth, while at the same time new bone is developed beneath the periosteum. Thus, even when the tumour greatly exceeds the normal bone in size, it is often found to be still surrounded by a shell of osseous tissue.

Syphilitic Osteitis has already been described (Vol. I., p. 1157).

**Necrosis of the Compact Tissue** may be the result of direct injury, as a severe blow. A portion of bone may perish owing to its vascular supply being cut off by separation of the periosteum by injury or by the formation of pus beneath the membrane; and in like manner suppuration in the medullary canal may cause the death of the neighbouring compact tissue. When the compact tissue becomes involved in acute inflammation extending to it, either from the medulla or from the periosteum, it is very apt to necrose from pressure upon the vessels in the Haversian canals by the inflammatory exudation within them. Chronic osteoplastic osteitis may also, in some cases, end in necrosis from gradual obliteration of the Haversian canals. It is quite possible that small fragments of bone may die and subsequently be absorbed; but that this may take place it is necessary that the dead portion be of small size and free from irritating properties. If it have perished in consequence of some infective inflammation, or have been impregnated with decomposing matter, its absorption becomes impossible, for absorption of bone is carried out solely by the medium of the living cells before described, and these cannot exist in a healthy state in the presence of the virus of an infective process or the products of putrefaction. Larger fragments of dead bone are always separated from the living and cast off. This is accomplished entirely at the expense of the living bone. The process by which it is carried out is merely one of rarefying osteitis carried to its highest stage, and ending in complete destruction of the osseous tissue where the living is in contact with the dead, its place being occupied by granulation tissue. The layers of this tissue touching the dead bone break down into pus, and thus complete separation is accomplished. The further details of the process will be given when treating of necrosis clinically.

**INFLAMMATORY PROCESSES IN THE MEDULLA OF LONG BONES.**—The marrow of a long bone is composed of fat, supported by a delicate connective tissue and traversed by vessels. It contains numerous cells resembling white corpuscles. In contact with the solid bone the connective tissue assumes an imperfect membranous form and is more abundantly vascular, and this layer has received the name of the medullary membrane. It is unnecessary to enter into any great detail in describing the inflammatory processes that occur in the marrow of bone, as they are the same as in other soft structures. The forms of inflammation occurring in the medulla are the following:—(1) Simple acute osteomyelitis. (2) Diffuse acute osteomyelitis; (*a*) septic, (*b*) infective. (3) Chronic osteomyelitis; (*a*) simple, (*b*) tuberculous.

**Simple Acute Osteomyelitis** is usually of traumatic origin. The phenomena observed are the same as in other soft parts, viz., dilatation of the vessels, exudation and migration of the corpuscles, and gradual disappearance of the normal tissues before the new cells. In compound fractures and amputations it occasionally ends in suppuration, a small collection of pus sometimes forming which discharges itself through the open end of the medullary canal. In simple fractures suppuration never takes place, but the products of the process are developed into bone, thus forming the internal callus (*vide* Repair of Fracture, Vol. I., p. 529).

Osteomyelitis in its early stages is recognized by the dark red colour of the marrow. Later on the fat disappears, and soft tissue, having the ordinary pink colour of granulation tissue, takes its place. If bone forms it appears first in contact with the pre-existing osseous tissue.

**Acute Diffuse Osteomyelitis** is one of the most serious affections of bone. It occurs in two forms, traumatic and idiopathic. The traumatic is usually of septic origin, and is the direct consequence of decomposition of the discharges in a wound communicating with the medullary canal, as in a compound fracture or amputation. The products of putrefaction diffuse themselves in the soft tissue of the medulla and set up acute inflammation, which rapidly ends in suppuration, and often in gangrene of the marrow. There is nothing peculiar about the process, beyond the fact that the products, being enclosed by the surrounding solid bone on all sides except at the opening into the canal, tend to diffuse themselves rapidly, often extending to the cancellous tissue at the articular ends.

Acute diffuse osteomyelitis may result also from the virus of the various infective inflammations which attack wounds, as erysipelas, hospital gangrene, &c., finding admission to the medullary canal. The distinction between these specific inflammations and that arising from the irritation caused by the products of simple putrefaction cannot usually be made, as it may be said that infective traumatic osteomyelitis never arises when the discharges of the wound are in an aseptic condition.

**Idiopathic Infective Osteomyelitis** is rarely met with, in this country at any rate, but is described as of frequent occurrence by most German writers; in fact, the cases which most English pathologists describe as acute infective or suppurative periostitis, or as acute necrosis, are by German writers spoken of as acute osteomyelitis. Infective osteomyelitis has been induced artificially by injuring a bone subcutaneously and then injecting putrid fluids containing microscopic organisms into the blood-stream. In the human subject the pus from bones affected in this way can always be shown to contain micro-organisms. The form always met with is *staphylococcus pyogenes* (see Vol. I., p. 243). The virus is believed to be carried by the blood to the affected bone. What it is that determines the particular bone affected when the inflammation commences in the medulla is uncertain, but when the periosteum is primarily affected, and the medulla only implicated by extension through the compact tissue, the origin of the process can often be traced to a blow.

A bone affected with acute diffuse osteomyelitis of any form presents the following appearances on section. The medulla is in parts redder than natural, and scattered hæmorrhages are commonly met with. In other parts it is paler in colour and infiltrated with pus, which here and there is collected in abscess-cavities of various sizes. At each end of the bone the morbid condition extends into the cancellous tissue, the marrow in the spaces presenting the same appearances. If the osteomyelitis is of the traumatic septic form, grey gangrenous patches are usually present, and the sawn bone is abominably offensive to the smell. The compact tissue shows no definite

Fig. 504.—Diffuse Osteomyelitis of Humerus, after Excision of the Elbow-Joint.

changes, but the periosteum is always swollen and frequently separated from the bone by the formation of pus beneath it.

Acute diffuse osteomyelitis always causes more or less extensive necrosis of the compact tissue, partly by depriving it of its vascular supply when suppuration takes place, and partly from extension of the diffuse inflammation into the Haversian canals. The veins of the affected bone become inflamed and filled with coagulum. The thrombi being invaded by the infective material, soften and disintegrate, and the fragments bearing with them the infective matter are carried into the circulation, and thus embolic pyæmia is a very common result.

**Simple Chronic Osteomyelitis** occurs only as a part of more general inflammatory affections of bone. Thus, in an osteoplastic osteitis, we often find the medullary canal encroached on by the newly-formed osseous tissue, until in some cases it is completely filled by spongy bone. In necrosis of the compact tissue the neighbouring medulla becomes chronically inflamed, and the products of the process undergo ossification.

**Tuberculous Osteomyelitis** results from the deposit of tubercle in the medulla, and must be recognised as a distinct variety of tuberculosis of bones. The condition is seen most frequently in the metacarpal bones and phalanges, and it is here spoken of clinically as strumous dactylitis. It usually results in the formation of a more or less diffuse caseous mass in the interior of the bone. Sooner or later the compact bone is slowly perforated by a process of rarefactive osteitis, and thus a chronic abscess forms beneath the periosteum, and gradually invades the superficial tissues. The shaft is often thickened by a deposit of new bone beneath the periosteum. Necrosis often occurs, and the sequestrum may present any of the characters met with in tuberculous disease of cancellous bone. In addition to those cases in which a primary tuberculous osteomyelitis occurs, it occasionally happens that the medulla is invaded secondarily from a primary focus of disease in the extremity of the bone.

**INFLAMMATORY AFFECTIONS OF THE CANCELLOUS TISSUE.**—The cancelli of the spongy tissue of bone are composed of osseous tissue differing in no respect save in its arrangement from the compact substance. The spaces are filled with a marrow in most parts identical with that of the medullary canal, but containing less fat. In the vertebræ, ribs, and diploë of the skull, the marrow is red, and contains numerous cells like white corpuscles and others apparently intermediate between white and red. There is no reason to believe that any of the pathological changes observed in cancellous bone begin in the osseous tissue, the starting-point of every process, as far as can be ascertained, being the medulla filling the cancellous spaces. The following are the chief inflammatory processes met with in the cancellous tissue:—1. Acute diffuse osteitis; 2. Rarefactive osteitis; 3. Osteoplastic osteitis. Chronic inflammation of cancellous bone is in the large majority of cases tuberculous.

**Acute Diffuse Inflammation of the Cancellous Tissue** is the same process occurring in the medulla of the cancellous tissue as has already been described under the name of acute diffuse osteomyelitis when attacking the marrow of a long bone, and arises under similar conditions, either as the result of the contact of putrid discharges in an open wound, implicating the spongy tissue of a bone, or as an infective process commencing without direct communication with the external air. In many cases it is merely an extension to the ends of the bone from the medullary canal. In it the cancellous spaces

become filled with pus, or the medullary tissue may become gangrenous. It always leads to necrosis of the osseous tissue surrounding the spaces.

**Rarefying Osteitis** is very common in spongy bones, and forms the chief pathological change in a large proportion of the cases clinically spoken of as *caries*. Rarefying osteitis in cancellous bone is essentially the same process as in the compact tissue. Inflammatory exudation and migration of white corpuscles take place in the medullary tissue, and the original structures disappear before the inflammatory new growth (Fig. 505). The cancelli become gradually thinned, being absorbed in exactly the same way as the lamellæ of the compact tissue. A spiculum of bone removed from the inflamed area shows the same irregular excavations or Howship's lacunæ, in most of which osteoclasts may be seen. The bone-corpuscles have frequently undergone fatty degeneration: sometimes the cells in the lacunæ are represented merely by oil globules. This is due to interference with the nutrition of the osseous tissue consequent on the changes occurring in the medulla of the cancellous spaces. Finally the bony tissue in the affected area may entirely disappear, the whole space being occupied by soft vascular granulation tissue.

**Osteoplastic Osteitis** affects the cancellous tissue with considerable frequency. It is characterized by thickening of the cancelli by formation of new bone upon them at the expense of the medullary tissue.

The spongy bone thus becomes gradually denser in structure till it may closely resemble compact bone. The process of formation of the new bone is the same as in other parts. Osteoplastic osteitis of the compact tissue is often met with at the circumference of an area in which the rarefying process is going on, and thus not uncommonly a dense zone of bone is formed round a chronic abscess or a sequestrum. It is met with also in conjunction with chronic inflammatory processes in the compact tissue and in the neighbourhood of sequestra. In other cases it may occur as a sequence of the rarefactive inflammation, the formation of new bone on the cessation of that process exceeding the normal limits.

**Tuberculous Disease.**—We have already seen that tubercle of bone may in certain instances commence as a periostitis or as an osteomyelitis. Far more common, however, is its occurrence in the cancellous tissue of the articular extremities of the long bones, or in that of irregular bones, such as the vertebrae and tarsus. Indeed, it is now a generally accepted fact that the different varieties of chronic inflammation of cancellous tissue—rarefactive and osteoplastic—are in the large majority of cases dependent upon a tuberculous deposit in the bone. Microscopic examination of the granulation tissue which fills the cancellous spaces shows the characteristic appearances which have

Fig. 505.—Carious bone from a Case of Tuberculous Osteitis of the bones of the Skull in a child. At *a* are seen the so-called Lacunæ of Howship; the material filling the dilated Cancellous spaces *a* is caseous granulation tissue.

already been described (Vol. I., p. 1086). The tubercle often assumes the infiltrating form, although definite tubercle nodules may be present. The disease spreads by a process of rarefactive osteitis until a considerable caseous mass occupies a cavity in which the bony trabeculae have been completely destroyed. The nature of the changes in the bone has been carefully studied by Watson Cheyne. Around the tuberculous focus the cancellous spaces are filled with vascular fibrous tissue, and the trabeculae themselves are generally more or less thickened. As the disease spreads, the fibrous material is invaded by the tuberculous granulation tissue, and the sclerosed trabeculae are absorbed. In this way the surface of the bone is gradually reached, and infection of the superficial structures or the cavity of a joint occurs. Cheyne has also pointed

Fig. 506.—Tuberculous cavity in Head of Tibia.

Fig. 507.—Chronic rarefactive osteitis of the Cancellous Tissue, with caseation of the inflammatory products.

out that a condition of rarefactive osteitis may be met with in parts of the bone at a considerable distance from the focus of disease.

The following are the most important modifications which are met with in tuberculous disease of cancellous bone :—

(a.) *Caries with suppuration.* In this condition, which is the commonest form, chronic suppuration results from the admixture of the caseous tubercle with the inflammatory exudation of the surrounding tissue. When the disease reaches the surface of the bone the periosteum is first raised by the pus and subsequently perforated, the chronic abscess then finding its way to the surface.

(b.) *Chronic abscess of bone.* In this condition caseation and suppuration occur after the complete destruction of the osseous cancelli. Osteoplastic osteitis slowly proceeds in the surrounding bone until the pus is completely shut in by a dense layer which offers great obstruction to the spread of the suppuration. In this way a small collection of pus may remain permanently encysted in the centre of the bone, or eventually it may come to the surface through a fine track and discharge itself beneath the periosteum.

(c.) *Caries sicca* or *dry caries*. In this variety of caries extensive destruction of the bony matter may occur without suppuration, the granulation tissue being in part absorbed and in part undergoing ossification. Dry caries is most commonly met with in the bodies of the vertebræ, and occasionally in the articular surfaces of bones, as, for instance, in the head of the humerus.

(d.) *Caries fungosa* or *fungating caries*. This name has been applied to those cases in which the granulation tissue grows exuberantly, with rapid destruction of the bony cancelli. It is most common in the articular ends of bones; the granulation tissue fungates into the joint, after destruction of the cartilage, and leads to secondary infection of the synovial membrane.

(e.) *Necrotic caries* is a very common result of tuberculous disease of cancellous bone. In the process of rarefactive osteitis above described the destruction of the bony trabeculæ takes place by gradual absorption through the agency of osteoclasts. Almost invariably, however, minute fragments of bone are found in the tuberculous tissue and represent portions of cancelli which have become completely separated, and are indeed minute sequestra. In necrotic caries this same process occurs in a more marked degree, and thus we find in the cavity of the chronic abscess, or imbedded in a mass of caseous material, a portion of necrosed cancellous bone often of considerable size. The sequestrum is soft and spongy as the result of the rarefactive osteitis which had already in part destroyed it; its enlarged cancellous spaces being occupied by granulation tissue.

In another variety of necrosis due to tuberculous osteitis the sequestrum presents characters quite different from those above described. Instead of being soft and spongy it is very dense and sclerosed, the microscope showing that the trabeculæ are much thickened, and the cancellous spaces occupied by tuberculous tissue which may be calcareous. The separation of such a sclerosed area of bone as a sequestrum depends upon the spread of rarefactive osteitis around it with destruction of all its connecting trabeculæ. Sequestra of this kind are most commonly found in the articular extremities of bones. They are often superficial, and more or less wedge-shaped, so that König has suggested that they are the result of embolism. This view cannot be accepted, for, as Cheyne remarks, it fails to explain the fact that the bone shows unmistakable evidence of the active growth which preceded its death.

When tubercle of bone becomes quiescent or undergoes cure, condensation of the rarefied bone takes place, and the tuberculous granulation tissue undergoes fibroid degeneration or becomes calcareous. Remains of the tubercle may however sometimes be found at long periods after all evidences of active disease have disappeared, a fact which is in keeping with the well-known tendency of the disease to recur after years of apparent cure.

It is necessary here to state that the term **Caries** is applied to any chronic destructive inflammation of bone whatever its cause may be. Caries is not a disease, but is the result of various conditions which lead to rarefactive osteitis, with or without suppuration. Tubercle is undoubtedly by far the most common cause of this destructive inflammation of bone, and it will be convenient to state the various facts upon which this view is based. In the first place, the histological characters of the granulation tissue which occupies the cancellous spaces and the various changes which it undergoes are in every respect similar to those met with in tuberculous tissue elsewhere. Secondly, the tubercle bacillus can usually be demonstrated in the diseased tissues if

a prolonged search be made. The bacilli are, however, few in number, and it is interesting that Watson Cheyne has found much difficulty in demonstrating them in cases of tuberculous joint disease artificially produced in animals by inoculation with pure cultivations of the organism. Thirdly, the bone and joint affections in question are not uncommonly associated with tubercle of the lungs and other organs. Billroth found cheesy tuberculous deposits in internal organs in 54 per cent. of the cases of caries examined by him. The lungs were most commonly affected. It is probable that in many of these the general infection was secondary to the disease of the bone, though it is quite possible that in many the reverse may have been the case. Death from other tuberculous affections is by no means rare, and general tuberculosis has been known to follow operations undertaken for the cure of the local disease. Fourthly, exactly similar changes in bones have been produced experimentally in animals by injecting into them phthisical sputum, and the pus from chronic abscesses. Lastly, Watson Cheyne has produced the typical "strumous" diseases of bones and joints by the inoculation of pure cultivations of bacilli obtained from human tuberculosis. In the case of the bones the bacilli were injected either into the blood-vessels supplying the bone, or directly into the epiphyses or medulla. Tuberculous inflammation followed, with, in some cases, typical disease in the neighbouring joints, expansion of the bone and the formation of new bone beneath the periosteum.

#### CLINICAL FEATURES OF THE INFLAMMATORY AFFECTIONS OF BONE PERIOSTITIS.

**Inflammation of the Periosteum** is common as a result of injury, syphilis, or articular rheumatism. Of these causes rheumatism is the least common, but the existence of a true rheumatic periostitis cannot be doubted. Three cases of this nature have recently been recorded by Conlts and Garrod: in all the periostitis affected the ulna, and was associated with organic heart disease, joint swellings, and subcutaneous rheumatic nodules. Periostitis occasionally occurs as a sequela of other acute specific diseases, such as typhoid and scarlet fever. It may be dependent upon disease of the subjacent bone, and frequently occurs in the neighbourhood of joints as the result of extension from the inflamed ligaments.

**Symptoms.**—*Simple Acute Periostitis* (p. 256) resulting from injury, such as a blow on a superficial bone, as the tibia, is characterized by the formation of a swelling, fixed on the surface of the bone, acutely tender, and accompanied by severe tensive aching pain, especially when the limb is in a dependent position. The skin may be slightly reddened and cedematous. Under proper treatment the symptoms soon subside in most cases, but occasionally the inflammation goes on to suppuration. In simple periostitis the pus shows but little tendency to burrow beneath the membrane, in this differing essentially from the diffuse or infective subperiosteal suppuration to be described presently (see *Acute Infective Periostitis*). The simple subperiosteal abscess may be followed by necrosis of a scale of bone, but more commonly after the pus is evacuated it heals without further trouble.

*Subacute and Chronic Periostitis* may occur as a sequel of the acute form, just described; or the disease may from the beginning assume this form when

it is due to syphilis, rheumatism, or occurs in a scrofulous subject. Chronic periostitis is always accompanied sooner or later by the formation of new bone (Osteoplastic Periostitis, see p. 257). The symptoms consist of a hard elongated, but somewhat puffy swelling without cutaneous discoloration—a *nodule*—not distinctly circumscribed, and attended with much pain in the part, especially at night, with tenderness on pressure.

**Treatment.**—In the treatment of the *acute form* of the affection, the free applications of leeches, with hot fomentations, will arrest the disease, and give relief to the patient. Should pus form it must be let out by incision as soon as it is recognized, strict antiseptic precautions being observed in order to diminish the risk of necrosis.

In the more *chronic form*, the continued administration of the iodide of potassium will reduce the swelling, remove the nocturnal pains, and materially improve the local condition of the part. In those cases of periostitis which are of syphilitic character, iodide of potassium may be looked upon almost as a specific. Added to this, repeated blistering will be of essential service. If there be much thickening, the parts suffer from the tension of the structures; here considerable relief will be afforded by the free division of the periosteum down to the bone, either through the skin, or subcutaneously by means of a tenotome.

#### CHRONIC OSTEITIS AND PERIOSTITIS.

By **Chronic Osteitis and Periostitis** is meant an affection usually attacking long bones, leading to considerable enlargement, with alteration in structure. A section of the affected bone shows that the periosteum is thickened and new bone is being formed beneath it (Osteoplastic Periostitis, p. 257). The compact tissue has become more porous than natural, and from the simultaneous destruction of the old bone and formation of new, it often shows a peculiar laminated expansion of its structure, so that a section of it presents an appearance of concentric parallel layers (Rarefying Osteitis and Expansion of Bone, pp. 261, 265). The cancellous tissue may at the same time become denser than natural, and new bone may form, filling the medullary canal (Osteoplastic Osteitis of the Cancellous tissue, p. 265). As the result of these changes in its various component parts, the whole bone may be converted into a uniform mass with but little distinction between the cancellous and compact tissue. When the process becomes extremely chronic, as it often does, the osteoplastic processes may be more pronounced, and the enlarged bone may become extremely dense and ivory-like in structure. Chronic osteitis and periostitis may occur alone, but it is more common to find them associated with necrosis of small portions of the cancellous or central layers of the compact tissue, or with the presence of a chronic abscess in the cancellous tissue. The disease may affect the whole length of a bone (Fig. 509), or may be limited to one end. When it occurs in young subjects it is often accompanied by early union of the epiphyses, which may cause shortening from want of growth. In other cases in which the middle part of the bone is chiefly affected, elongation may take place. I have seen, as the result of chronic osteitis, the tibia from one-and-a-half to two inches longer than its fellow.

**Causes.**—Chronic osteitis may arise from various causes. In some cases it is met with in strumous children, and appears to arise from slight injury

or from exposure to cold. In those cases in which it is limited to one end of a bone, it is often due to the irritation caused by the presence of a small tuberculous centre deeply seated in the cancellous tissue. When the middle part of the bone is affected, especially before cessation of growth, it will not uncommonly be found to be due to hereditary syphilis. In adult life it is often one of the effects of acquired syphilis.

**Symptoms.**—The symptoms of chronic osteitis consist of enlargement of the affected bone, with deeply seated pain in and great tenderness of the limb; the pain, as in periostitis, is greatly increased at night, and, when the disease is chronic, is much influenced by the state of the weather. There is no danger connected with this condition; but it often becomes distressing from the severity of the tensive and nocturnal pain accompanying it. In strumous subjects there is always considerable probability that the condition is secondary to a central tuberculous focus, and this may lead to necrosis or caries with chronic suppuration.

**Treatment.**—In chronic osteitis and periostitis, when the bone has become thickened and enlarged, but little can be done in the way of cure. The administration of iodide of potassium with occasional application of blisters will however do much to arrest the progress of the disease and relieve pain, especially in those cases in which there is a syphilitic taint. Should these means fail to give relief, and the pain continue of an excessively distressing and persistent character, I have found the operation of *linear osteotomy* of great service. An incision about three inches long is made directly down on the chronically inflamed and indurated bone, being carried through the periosteum, so that the scalpel grates upon the bone. By means of a Hey's saw this cut is extended into the substance of the bone as far as the medullary canal, or deeply into the cancellous tissue. Some bleeding occurs, but it can always be arrested by position and pressure. The wound is then closed. In this way tension is taken off; and the pain, which appears to be dependent on the compression of inflamed bone by its own condensed structure, is at once relieved. "Linear osteotomy" is an operation especially applicable to osseous nodes of the long bones, or to chronic osteitis of the articular ends of the tibia, and is a far less severe mode of treatment than trephining the bone, which has occasionally been adopted in such cases; while it is equally efficacious. After a time, when the progress of the disease ceases, the enlarged bone does not give rise to any very serious inconvenience, except such as may be occasioned by its bulk.

#### CHRONIC ABSCESS OF BONE.

**Chronic abscesses in bone** are usually met with in the cancellous tissue, and occur with special frequency in the head and lower end of the tibia. The abscess forms as the result of rarefying osteitis of a localized portion of the cancellous tissue (p. 265). This process continues till the bony cancelli are completely destroyed. Subsequently the inflammatory products undergo fatty degeneration and soften, forming thick curdy fluid containing few recognizable pus cells and large quantities of fatty *débris*. The process may continue gradually to extend, and may thus undermine the contiguous cartilage, and eventually the abscess may burst into the neighbouring joint (Fig. 508). The tendency for the pus to burrow in this direction is increased by the want of formation

new bone beneath the cartilage, while it readily takes place under the tendons. In young subjects before the union of the epiphyses, the abscess commonly finds its way to the surface through the soft tissue between the epiphysis and the diaphysis. Very frequently, however, the disease becomes excessively chronic. The abscess is then of small size and deeply seated in the cancellous tissue. The inflammation in the bone immediately

Fig. 508. — Abscess in the Head of the Tibia.

surrounding the cavity in these cases often assumes the plastic form, and the collection of pus becomes enclosed by a wall of excessively dense hard bone, and in this state it may remain unchanged for many months or even years. The irritation caused by the presence of pus usually gives rise to chronic inflammatory changes in the neighbouring compact tissue and periosteum. These changes assume the form described in the previous page as "chronic osteitis and periostitis," and produce considerable enlargement of the affected end of the bone. Chronic abscesses have occasionally, but more rarely, been met with in the medullary canal.

The quantity of pus contained in a chronic abscess of bone is usually very small, amounting to one or two drops, but Stanley has recorded cases in which an ounce or more was found.

It may happen that degeneration of the inflammatory process or suppuration may take place before the healing process has advanced far enough to cause complete destruction of the cancellous tissue. The undestroyed bone then perishes, becomes detached from the surrounding parts, and lies loose in the cavity of the abscess.

In some cases abscess of bone is associated with chronic osteitis of a considerable portion or the whole of the shaft, the bone becoming greatly thickened, and generally diseased from end to end. Fig. 509 is a representation of a section of the tibia in such a state of combined suppu-

Fig. 509. — Section of Tibia, showing Chronic Osteitis and Circumscribed Abscesses of many years' duration.

ration and inflammatory hypertrophy, removed by amputation from a woman who had suffered for twenty-three years from the disease.

The **Causes of Chronic Abscess of Bone** are often somewhat doubtful. It occurs almost exclusively in scrofulous subjects, and there can be no doubt that the immediate cause in a very large proportion of cases is the deposit of tubercle in the medulla of the cancellous tissue. This sets up inflammation around it, and finally softens in the same way as in other parts. In some cases the disease arises apparently from injury.

The **Symptoms** of chronic abscess of bone are usually of the following character. The patient, perhaps after the receipt of an injury, has noticed that at one spot the affected bone has become swollen and painful; the skin covering it preserves its natural colour in the majority of cases, but in some instances becomes red, glazed, and cedematous; the pain, which is of a lacerating and aching character, is usually remittent, often ceasing for days, weeks, or months, and then returning, under the influence of very trivial causes, with its original severity. It is especially troublesome at night, and is always associated with a degree of tenderness of the part; and, indeed, in the intervals of its accession, it will be found on careful examination that there is always one tender spot in the enlarged and indurated bone. The long persistence, for years perhaps, of these signs will usually point to the existence of a small circumscribed abscess under the thickened wall of the bone. It must be borne in mind, however, that the same local symptoms may be induced by four conditions: 1. By a chronic abscess without necrosis. 2. By the inclusion of a small piece of dead bone surrounded by pus within a dense and impervious casing. 3. By simple or syphilitic osteitis and periostitis (p. 269, and Vol. I., p. 1157), without suppuration or necrosis; and, 4. By the growth of a tumour within the bone. For all practical purposes the diagnosis is of little consequence, as the operative procedure is the same, whether the symptoms arise from the confinement of a few drops of pus or from the inclusion of necrosed bone, and the diagnosis of the presence of a tumour can often be made only by a similar operation.

The danger of chronic abscess of the end of a long bone will greatly depend on its proximity to the articular surface. If near this, it will probably lead to perforation of the cartilage, so that the pus enters the joint, which then becomes acutely inflamed and often destroyed. If the abscess is due to the presence of softening tubercle the synovial membrane may become infected, and chronic tuberculous disease of the joint may thus be set up.

If the chronic abscess be situated in the diaphysis near the junction of the epiphysis with the shaft, this event is not so likely to occur. The surrounding bone simply becomes thickened; and though the health may suffer from the constant wearing pain, the joint is not in peril, and relief may readily be given by operation.

**Treatment.**—As a circumscribed abscess in bone cannot perforate the dense osseous structure overlying it by any process analogous to the pointing and discharge of an abscess in the soft parts, it becomes necessary for the Surgeon to open up a vent for the pus. In some cases simple linear osteotomy, as described at p. 270, may be practised; but should the bone be much thickened and the osseous structures greatly indurated, an efficient aperture can only be made by means of the trephine or gouge. Before performing this operation the point of greatest tenderness should be accurately marked on the skin.

The limb having been made bloodless by Esmarch's method, the bone is exposed by a free incision over the tender area. The edges of the incision being held apart with blunt hooks, the periosteum is divided and reflected with a Langenbeck's (Fig. 510) or T-shaped elevator.

A bone trephine is then applied, or the dense bone may be carefully cut away with a gouge (Fig. 511) and mallet.

The diseased cavity will very commonly at once be opened in this way. It may contain curdy pus, and the sclerosed bone surrounding it may be covered with a thin layer of soft granulation tissue; or a sequestrum may be found surrounded by a layer of caseous tuberculous tissue. In either case the cavity must be thoroughly scraped out with a Volkmann's sharp spoon, and any overhanging bone should be removed with the gouge, so that, if possible, the opening may in every direction be as extensive as the cavity itself. If, however, no cavity be found the Surgeon must not be disappointed, but should pierce the neighbouring osseous tissue in different directions by means

Fig. 510.—Langenbeck's Periosteal Elevator

Fig. 511.—Gouge.

of a gouge, when perhaps the abscess will be opened; should it not be so, the patient will still in all probability be materially benefited by the removal of the circle of bone, and the consequent relief to the compression of the osseous tissue.

The operation should, if possible, be performed with antiseptic precautions. The cavity should be thoroughly cleaned with a small piece of sponge soaked in some antiseptic solution (as chloride of zinc, gr. xx. to 3j.), in order to remove any fragments of necrosed bone or saw-dust. It may then be dressed with any efficient antiseptic dressing, which should be firmly applied before the tourniquet is removed, the cavity in the bone being plugged with strips of gauze. At the subsequent dressings careful plugging will be required to prevent the superficial wound from closing before the deeper parts have healed.

In some cases, when the cavity is small, plugging is unnecessary, and a dry wool dressing may be left unchanged, if all goes on well, for a week or even a month if no discharge soaks through. If decomposition can be prevented the cavity often becomes filled with blood-clot into which the granulation tissue sprouts from the surrounding bone, until in two or three weeks it may be completely closed. If the cavity becomes filled with septic discharges the process of healing is much delayed. Subsequently the granulation tissue develops into bone and the limb recovers its former strength and utility.

## DIFFUSE SEPTIC OSTEOMYELITIS.

Diffuse acute inflammation, ending in suppuration of the medullary tissue of a bone, may arise as a consequence of open wounds, such as compound fractures or amputations, or may occur as an acute disease arising without evident cause. I shall here deal only with the former condition, the latter being most conveniently considered when discussing the affection commonly known in this country as "acute necrosis."

Diffuse septic osteomyelitis was formerly a common consequence of injuries by which the medullary canal was opened, such as compound fractures or amputations, and it was also often met with when the cancellous tissue only was implicated, as in excision of the knee. Compound fissured fractures of the long bones, such as result from gunshot wounds, are specially prone to be followed by it. The condition is essentially connected with decomposition of the discharges of the wound through which the bone has been exposed, and more especially with the presence of septic matter pent up in contact with the open medullary canal or cancellous tissue. The improved treatment of wounds and the use of antiseptics have now almost abolished it in civil practice though it is still not uncommon in military surgery.

In certain rare cases diffuse osteomyelitis has been met with as the result of subcutaneous injuries. In the majority of these cases it forms a secondary effect of general blood-poisoning from a foul wound in some other part of the body. That this is the most probable explanation of these cases is shown by the fact that simple fractures can be made to suppurate in animals, and osteomyelitis can often be induced in the injured bone by injecting septic matter into the blood-stream.

The pathology of the process is not difficult to understand. If septic matter be pent up in the deep parts of a wound in contact with the opened cancellous tissue or the medullary canal, the products of decomposition will readily diffuse themselves into the soft medullary tissue. This becomes acutely inflamed, and pus is rapidly formed; or owing to the confined space in which the medullary tissue is contained, the inflammatory swelling may arrest the circulation and cause gangrene. Whether it ends in gangrene or in suppuration the products of the inflammation in their turn decompose, and thus the process rapidly spreads throughout the medulla. Simple putrefaction is thus sufficient, in most cases, to explain the phenomena of diffuse osteomyelitis, without supposing that any specific virus is present. It is probable, however, that in many cases the wound is really infected with some specific virus analogous to that of phlegmonous erysipelas or spreading gangrene, for diffuse osteomyelitis may attack several patients in one ward at the same time, and, in fact, is predisposed to by all those conditions which have already been described as influencing the occurrence of other infective processes in wounds. The pus and gangrenous medulla are always found to contain microscopic organisms, but they are not uniform in character. The process is often accompanied by offensive decomposition and blackening of the gangrenous tissues from the generation of sulphuretted hydrogen. Septic osteomyelitis is one of the most common causes of embolic pyæmia. The connexion between these conditions has been specially pointed out by Fayrer, who has had abundant opportunities of studying the disease in India. The frequency with which pyæmia follows this affection is due to the fact that the

veins of bone, lying as they do in rigid canals, cannot collapse, a condition highly favourable to the extension of thrombosis. The thrombi thus formed become impregnated with the products of the unhealthy process, disintegrate, and are washed on into the blood-stream, causing centres of suppuration wherever they lodge. It is this that makes septic osteomyelitis a most dangerous and often fatal disease.

Fat-embolism has been observed in many cases of acute osteomyelitis, the liquid fat from the broken down marrow being forced into the vessels or lymphatics by the pressure of the inflammatory exudation. If the emboli are impregnated with the products of decomposition, they may give rise to abscesses in distant parts where they lodge.

If the patient escape the dangers of pyæmia, the disease almost invariably leads to more or less extensive necrosis affecting chiefly the inner layer of the compact tissue. The long sequestra once so frequent in stumps, especially after amputation of the thigh, were the result of this process (see Vol. I., p. 77).

After death, the appearances presented by the inflamed bone will, if it have been the seat of compound fracture, usually be most marked in the upper fragment; if it have been the seat of amputation or excision, they will extend through the whole of the bone that is left. The periosteum and outer surface of the bone will appear to be slightly injected. On making a longitudinal section of the bone, the medullary canal is found to be filled with pus or a reddish puriform fluid, often abominably offensive; the medulla is swollen, soft, pulpy, of a deep red or reddish-brown colour; the compact bone has a pinkish tinge, and the cancellous osseous structure is often of a bright rosy hue. In a case of compound fracture, the contrast between the deep coloration of the inflamed portion of bone and the naturally pallid appearance presented by that which is not diseased, and more particularly the deep red hue of the medulla in the one, and the pale yellowish waxy-looking fat filling the medullary canal in the other, is most striking. Fayer describes the medullary canal, in advanced stages of the disease, as being filled with a mass of dead blackened medulla, *débris* of bone, and pus.

**Symptoms.**—In acute osteomyelitis, after an injury to or an operation involving the bone, the limb swells, and there is deep-seated severe aching pain with much tenderness. Abscesses form, often unconnected with the original wound, and profuse suppuration is established. The suppuration may amount to many ounces of pus in the day, and the discharge is often dark-coloured and fetid. The soft parts retract from the bone, and this where exposed is dry, yellow and dead, being denuded of periosteum. Septic inflammation and suppuration of the diploë are not uncommon in head injuries. In such cases the scalp is swollen, the periosteum loosened from the bone, and the outer table dry and bare. If the outer table be cut away after death, the diploë will be found infiltrated with offensive pus.

The constitutional symptoms are those of severe septic fever. The temperature is seldom below 103° F. In many cases the symptoms soon become those of acute pyæmia. If the patient escapes pyæmia the fever subsides, and subsequent symptoms are merely those dependent upon the presence of the necrosed bone.

**Treatment** consists in supporting the patient's strength by a tonic and stimulating regimen, and by scrupulous attention to hygienic rules.

The less acute forms of the disease call for no treatment beyond attention to cleanliness while the sequestra are becoming loose enough for removal.

In the more acute forms which threaten to terminate in pyæmia, nothing can be done so far as the affected bone is concerned, except its removal; but whether this should be done in the continuity of the bone or at the joint above, is a question on which different opinions are entertained among surgical authorities. If an operation be performed upon the continuity of a bone affected with diffuse suppuration in the medullary canal, the septic inflammation will almost certainly recur in the part of the bone which is left. Hence, it has been strongly urged by some Surgeons, especially by J. Roux, that the operation should be performed at the joint above the diseased bone, in preference to amputation through its continuity. Roux, who had extensive experience in the Italian war of 1859, successfully disarticulated the thigh at the hip-joint, in four cases of osteomyelitis consequent on gunshot injuries of the lower end of the femur. Of 22 cases in which he performed secondary disarticulation at other joints for osteomyelitis, all recovered; whereas every case terminated fatally in which the amputation was performed through the continuity of the injured bone after the battles of Magenta, Montebello, Marignano, and Solferino. On the other hand, Larrey did not consider disarticulation absolutely indispensable, even in cases of acute osteomyelitis; and Longmore has met with cases in which recovery has followed the simple removal of portions of dead bone—the disease in these instances having assumed a chronic form. Fayrer advises that, where osteomyelitis is suspected to be present in a stump after amputation, the medulla should be examined with a probe. If this soon impinge on healthy bleeding medulla, the Surgeon may wait for the efforts of nature to throw off the diseased bone; if, on the other hand, the probe encounter only dead bone and pus, then the sooner amputation is performed the better.

The special danger in osteomyelitis consists in the tendency to the super-vention of osteophlebitis and pyæmia; and, in deciding upon the amputation or exarticulation of a bone thus affected, it is of the first importance not to delay the operation until pyæmic symptoms have set in. There is a period between the development of the local inflammation and the pyæmic infection, which should not be allowed to pass. During this period the patient is affected by septic fever, but there are no rigors. If once the characteristic rigors and the irregular temperature and profuse sweats of pyæmia have set in, I believe that operation can be of no use, as the patient will certainly perish from secondary abscesses or general blood-poisoning. But, before rigors have occurred, the amputation may be done with a good prospect of success. The unsuccessful results of the treatment of this disease render it all the more imperatively necessary to prevent it by the adoption of efficient antiseptic dressing and proper attention to the hygienic surroundings of the patient. In military practice, however, this is not always possible.

It has been suggested, instead of amputating at once, to scoop out the medulla with a sharp spoon and to introduce iodoform into the canal. Perkowski has recorded 8 cases in which he carried out this treatment when the symptoms of osteomyelitis had set in after amputations. In three the whole of the medullary canal remaining was scraped out, and in the other five a length of from  $1\frac{1}{2}$  to 3 inches was treated in this way; all recovered without

pyæmia. The treatment certainly deserves a trial when amputation is for any reason unadvisable.

## ACUTE NECROSIS.

ACUTE NECROSIS is an acute infective inflammation almost exclusively met with before the growth of the skeleton is complete. The affection is known by many other names, such as acute diffuse periostitis, phlegmonous periostitis, infective periostitis, infective periostitis and osteomyelitis, acute infective osteomyelitis, acute suppurative epiphysitis, necrosial fever and bone-typhus; but the term "acute necrosis" is perhaps the best in the present state of our knowledge, as it does not imply any theory as to the exact nature of the disease and starting-point of the inflammation.

**Symptoms.**—A typical case of acute necrosis presents the following symptoms. The patient is usually a child below the age of puberty, and most commonly a male. He is often strumous and usually in somewhat feeble health, possibly the result of a recent attack of some acute specific disease, as scarlet fever or measles. There is in most cases a history of some slight injury, but this is by no means constant. The attack begins with a sudden invasion like that of a specific fever. There is high temperature, often reaching 105° F. or even higher, occasionally with a rigor or convulsion. Headache, loss of appetite, thirst, and sometimes vomiting or diarrhoea are present. At first the local affection may escape observation, and such cases are not unfrequently mistaken at the commencement for one of the acute specific diseases. By the second or third day, however, the local symptoms become manifest. The parts covering one of the long bones, most commonly the tibia, femur or humerus, are found to be swollen and acutely tender. At first the skin is pale, but it soon becomes reddened. By the fourth or fifth day, or sometimes not till the end of a week, distinct fluctuation is recognized, often extending over the whole of the shaft of the affected bone. At this time on moving the limb, distinct, though somewhat soft crepitus may be felt, and it will then be found that one or sometimes both the epiphyses may be loosened from the diaphysis. As a rule the joints escape, but occasionally one or both of the articulations into which the bone enters become distended with fluid. If at this stage an incision be made into the swollen parts down to the bone, a large quantity of pus escapes, and on inserting the finger the greater part of the diaphysis may be felt to be denuded of its periosteum. All this time the febrile disturbance persists, and by the end of a week may assume the ordinary characters of pyæmia. Symptoms of pneumonia, pleurisy and pericarditis and endocarditis may supervene and death take place before the abscess has been opened. The disease does not, however, always run this typical course. The following are the chief modifications met with. The threatened suppuration in some very rare cases does not take place. The inflammation of the periosteum gradually subsides in intensity, and assumes the osteoplastic form. A case of this kind occurred lately in University College Hospital in a youth aged about 19. No suppuration took place, the acute symptoms rapidly subsided, and the femur became gradually enlarged to more than double its natural size throughout the whole shaft, from formation of new bone under the periosteum. In other cases, although pus forms early, the extent to which the periosteum is raised from the bone is more limited, being confined to one end or the middle

of the shaft. In these cases the course of the disease is usually less acute, and the abscess may become localized and gradually point towards the surface. Separation of the epiphyses is by no means a constant occurrence; the younger the patient the more likely is it to occur. Billroth states that a disease of exactly the same character may occur in adults, but this is somewhat doubtful.

**Pathology.**—Acute necrosis must be regarded as an example of an acute infective suppurative and not as a specific disease. The fact that the pus in acute necrosis contains micrococci was demonstrated by Lücke and Klebs as long ago as 1874. In 1880 Pasteur cultivated the organisms obtained from a case of this disease, and pointed out their similarity or identity with those he had found in common boils; and the further researches of Becker in 1883, and Rosenbach in 1884, added greatly to our knowledge of the characters and properties of the micrococcus. Indeed it is now recognized that the organism is most commonly the *staphylococcus pyogenes aureus* or *albus* (Vol. I. p. 243), which is by far the most frequent cause of all forms of acute suppuration. The *streptococcus pyogenes* is much less commonly met with, but it has been found in some instances by Lannelongue and Achard. Reference has already been made to the experiment of Garre, who, by rubbing a pure cultivation from a case of acute necrosis into his arm, caused the development of a crop of boils.

The starting-point of the acute suppuration probably varies, but in the majority of cases it begins either beneath the periosteum or between the diaphysis and the cartilage of the epiphysis. In Germany and France the disease is more commonly described as acute osteomyelitis, and the suppuration is believed to commence in the medulla. There is no doubt that in fatal cases it is very common to find the medulla inflamed and often suppurating, but this is by no means constant, and in many cases at least is evidently secondary. In a case which lately occurred in University College Hospital, a section of the bone showed the medulla to be inflamed on one side only, in contact with the part of the compact tissue which was denuded of its periosteum, the remainder of the marrow being perfectly healthy. The inflammation was evidently of a more recent date than that of the periosteum. In the early stages it may be possible to decide whether the suppuration began beneath the periosteum or between the diaphysis and epiphysis, but soon all evidence of the starting-point is lost, for the pus completely separates the periosteum and causes separation of each epiphysis.

The mode of entrance of the organism into the body and its habitat out of the body are still uncertain. In very rare cases acute necrosis is preceded by an unhealthy wound or sore on the surface of the body, but, as a rule, no such source of infection is present. If the conditions for its development are not favourable, the organism is destroyed in the blood. On the other hand it may find a suitable nidus for its growth in one of the bones. The two parts of the bone in which the suppuration usually commences are both rich in vascular growing tissue and thus are especially liable to damage from trivial injuries. A definite history of injury is not uncommon in cases of acute necrosis, and the injury must be regarded as an important element in preparing the delicate growing bone for the growth of the organism. This clinical fact is in keeping with the results obtained by the experimental inoculation of animals with the *staphylococcus*; for it has been found that if,

before the injection is made, one of the long bones be bruised or broken, suppuration follows at the seat of injury.

Further observations are required in those cases in which suppurative periostitis follows acute specific diseases, such as typhoid and scarlet fever. These are probably examples of acute necrosis in which the organisms of suppuration have gained access to the blood through one of the local lesions of the acute specific, such as a typhoid ulcer. Achalmé has, however, recorded a case of abscess of the tibia following typhoid fever, in which the pus contained only bacilli, in every respect similar to those which are supposed to cause that disease.

The complications of acute necrosis can all be accounted for by the dissemination of the organisms of suppuration through the blood-stream. In some cases the secondary foci of suppuration are limited to the bones, but ordinary embolic pyæmia is not uncommon and results from infective phlebitis and thrombosis in the veins of the bone or of the soft parts around it. Small abscesses in the myocardium are especially common.

**Results.**—As the name “acute necrosis” implies, the disease almost invariably results in more or less extensive death of the compact tissue. The extent of the necrosis by no means necessarily corresponds to the area from which the periosteum has been raised by the pus, for after this has been evacuated, the membrane may adhere again to a considerable extent, and the connexion between its vessels and those of the bone be re-established. In a case lately in University College Hospital the tibia was felt to be bare from one end of the shaft to the other, yet after free incisions were made no necrosis followed, except over an area of about one square inch near the lower end. The after-history of the dead bone, the process of separation of the sequestrum and repair, will be fully described with necrosis in general.

**Diagnosis.**—Before the local symptoms become evident, especially in fat children, the disease is easily mistaken for one of the acute specific fevers. So likely is this to happen, that in cases of sudden severe febrile disturbance of doubtful nature in children, the bones should always be examined. When the swelling sets in, it may be mistaken for phlegmonous erysipelas or cellulitis, but these conditions are rare in childhood. When pus is suspected, a puncture should be made with a grooved needle or an aspirator, by which the diagnosis can usually be cleared up. When an epiphysis is separated the affection may be mistaken for disease of the neighbouring joint.

**Prognosis.**—The prognosis of acute necrosis is always grave, but as Billroth points out, it is probably not so fatal as hospital statistics would make it appear. The milder cases, in which the extension of the inflammation is limited, are often treated at home, and come under hospital treatment only at a later period, for removal of the sequestra. In fact, the great majority of cases of extensive necrosis of the long bones in young subjects are the result of this disease.

**Treatment.**—The only treatment is to cut down upon the bone and let out the pus at the earliest possible period. In the thigh the incision is best made on the outer side ; in the leg in front, over the tibia. If the lower end of the femur is chiefly affected the incision should be parallel to the anterior border of the biceps. In this way the ham may be opened up without endangering the synovial pouch of the knee. The incisions must be free, and if necessary several may be made. The wounds must be well drained and treated anti-

septicaemia. If the discharges be allowed to decompose, the danger to the patient will be greatly increased. The result of the treatment is to arrest immediately the constitutional symptoms and arrest the progress of the disease, but in a certain proportion of cases infection may have taken place before the disease is recognized, and the result is then fatal.

Fig. 512.—The diaphysis of the Tibia removed early in a case of acute necrosis. The whole shaft is not dead, but is partly covered by a thin adherent layer of new bone, shown on the left side of the figure.

If after the incisions have been made the discharge remains very profuse and threatens the patient, amputation may sometimes be necessary. In the arm or thigh, as there is only a simple abscess, a splint must be applied, lest spontaneous fracture should occur. If the shaft of the bone is exposed at each end from the epiphyses and lies in the cavity of the abscess, it becomes a question whether it should be removed at once or left in the limb. It may partly recover or may at least serve as a support during the formation of the new bone and the periosteum. Numerous cases have been reported by Holmes, J. Bell, Macnamara and others. Early removal has been practised with excellent results. Fig. 512 represents the shaft of the tibia removed in this way by C. Heath with a most satisfactory result. New bone is slowly formed from the periosteum. After a few months the limb is in most cases as strong as before the operation. The removal of the bone can usually be accomplished by simply making a free incision, laying hold of it with the forceps and twisting it out. In some cases the operation is facilitated by dividing the shaft into pieces with a saw. If the bone on examination is found to be firmly attached it should be removed.

It is only in those cases in which there is no union to believe that the whole diaphysis is separated from the periosteum at the epiphyses that the operation is justifiable.

#### CARIES.

We have already seen that the term **Caries** cannot be said to have a definite pathological meaning. It is in fact applied to every form of progressive ulceration of bone except that concerned in the separation of a sequestrum from the surrounding living bone. All these processes belong to the class of rarefying inflammations of bone, that is to say, the bone is gradually absorbed before an advancing inflammatory new growth can form from the vascular tissue, either in the medulla of cancellous bone or in the Haversian canals of compact bone. These processes have already been described (pp. 258, 262).

The modifications of caries depend upon the cause of the disease, the extent of the bone affected, and the stage of the process in which suppuration and degeneration of the inflammatory products takes place.

**Causes and Varieties of Caries.**—Caries may be divided as

its cause into *simple*, *syphilitic* and *tuberculous*. All forms are predisposed to by those constitutional conditions which predispose to inflammation generally. The disease is common in strumous subjects, in whom, as before stated (see *Scrofula*, Vol. I., p. 1095), inflammation is prone to be set up by slight causes and to persist.

Caries is divided also into *superficial*, *central*, or *articular*, according to the part of the bone which it affects.

In all forms of caries in which suppuration takes place as soon as the resulting abscess is opened, decomposition of the discharges ensues, unless precautions be taken to prevent it, and the irritation caused by the contact of the septic matter with the diseased surface tends to perpetuate the chronic inflammation and cause extension of the destruction of the bone.

In all cases of caries the neighbouring periosteum is swollen and thickened and new bone is formed beneath it. In central caries the compact tissue is usually somewhat rarefied.

**Situation of Caries.**—Billroth and Menzel of Vienna have examined the question of the relative frequency of caries in different bones. In 1,996 cases the numbers were: skull, 161; facial bones, 44; vertebral column, 702; sternum, clavicle, and ribs, 184; bones of shoulder-joint, 28; elbow-joint, 93; wrist and hand, 41; pelvis, 80; hip-joint, 189; knee-joint, 238; ankle-joint and foot, 150; scapula, 4; humerus (shaft), 13; radius, 2; ulna, 4; femur (shaft), 31; tibia, 30; fibula, 2. A classification in regions gives: head and spine, 1091; upper limbs, 185; lower limbs, 720. Hence it appears that while any bone may be affected with caries, it is most frequently met with in short and cancellous bones.

1. **Simple Caries** occurs under various conditions. When a joint has been wounded, and suppuration with destruction of the cartilages has taken place, the progressive ulceration that may occur in the exposed cancellous tissue is commonly spoken of as caries. In this case it is due partly to the irritation of the septic discharges, but chiefly to the friction of the diseased surfaces against each other. It seems probable, also, that in some cases of caries of the spine, the disease may originate in an injury of the soft growing tissue between the epiphyses and the body as the result of some concussion or forcible flexion. Owing to some constitutional weakness on the part of the patient, and still more to the slight mechanical irritation which must occur whenever the part is moved or the weight of the body thrown upon it, chronic rarefying osteitis may be set up, with progressive destruction of the bone. That the persistence of the process is in many cases due solely to the friction of the diseased surfaces upon each other is shown by the readiness with which cure takes place when this is prevented and perfect rest is obtained. Thus, in traumatic caries of a joint, if the limb be fixed so that all movement is impossible, or if the articular surfaces become separated by dislocation, the carious bone usually heals rapidly.

In these cases of simple caries if a section of the bone be made perpendicularly to the carious surface the disease will be found not to extend to any great depth. In the layer that is affected the bony cancelli are thinned and in part destroyed near the surface, so that in a macerated specimen the tissue looks more spongy than natural. In the spaces the normal medullary fat is replaced by granulation tissue.

In the *Treatment* of simple caries it is most important that the part should

be put at perfect rest. Thus if the osteitis be secondary to disease of a joint, this must be carefully fixed on a splint. Should there be an open wound strict attention must be paid to drainage, and to the prevention of decomposition in the discharges.

2. **Syphilitic Caries** has already been described (see Syphilis, Vol. I, p. 1159). It affects most commonly the surface of bones and is then the result of a softening subperiosteal gumma. The disease does not penetrate deeply, but leaves the surface rough and porous, and is accompanied by a good deal of inflammation of the soft parts around the affected bone. It occurs most frequently in adults and is very chronic. Like tuberculous caries it is occasionally complicated by necrosis of smaller or larger fragments of the affected bone.

Syphilitic caries is usually readily cured by the ordinary treatment of syphilis, iodide of potassium being especially useful, and by the application of iodoform or iodide of starch ointment.

3. **Tuberculous Caries.**—The evidence has already been considered which shows that by far the most common cause of the destructive inflammation of bone, which is known as caries, is the deposit of tubercle in it. The changes which tubercle produces in a bone have already been described under the separate headings of tuberculous periostitis, tuberculous osteomyelitis, and tuberculous disease of cancellous tissue. It now remains to indicate the symptoms and treatment of these different varieties.

It is a point of great practical importance that tuberculous disease of bones and joints frequently follows an injury. The association can hardly be accidental, and it seems far more likely that the simple traumatic inflammation predisposes the part to the growth of the tubercle bacillus, which reaches it through the blood-stream, often no doubt from some internal caseous centre.

In *tuberculous periostitis* attacking a superficial bone there will be a localized swelling over it, with, in most cases, some pain and tenderness. The superficial structures are at first normal, but later the skin becomes oedematous and discoloured, as the chronic abscess invades the soft parts and comes to the surface. If an incision be made it will be found that the periosteum is separated from the bone by curdy pus and granulation tissue. The surface of the bone is usually soft and roughened as the result of a superficial rarefactive osteitis.

In *tuberculous osteomyelitis*, such as so frequently affects the metacarpal bones and phalanges, gradual swelling of the bone is the most marked symptom. This is often remarkably painless, and in the early stages the superficial structures are normal; the movements of the adjacent joints are also very little interfered with. In some cases spontaneous cure takes place without suppuration, and the swelling of the bone slowly subsides, but in the majority of cases abscesses form over the bone, and having burst through the skin contract down to sinuses surrounded by prominent flabby granulations (Fig. 513). A probe passed down one of these sinuses will impinge upon rough carious bone and will often pass through a small opening into a central cavity perhaps containing a sequestrum.

The first symptom of a *tuberculous deposit in the cancellous tissue* of a short bone or of the articular extremity of a long bone is usually pain of a dull aching character. This may be associated with definite tenderness, probably the result of slight periostitis over the seat of disease. When the articular

extremity of a long bone is affected, the early symptoms may closely resemble those due to disease of the articulation itself. As the process of suppuration extends to the surface the skin becomes cedematous and inflamed, and finally a superficial abscess forms over the bone. When this has burst the character of the disease will be recognized, as the bare and rough bone may be felt with a probe, which sinks into depressions upon its surface, which though rough, yields readily to the pressure of the instrument. The cavity of the abscess gradually contracts, leaving sinuses, which discharge pus in varying amount. The discharge readily decomposes, unless means be taken to prevent this. Granules of bone, the minute sequestra from necrotic caries, are often intermixed with the discharge, which has been shown to contain a considerable excess of phosphate of lime. The sinuses are generally surrounded or concealed by high spongy granulations, and the neighbouring skin is dusky inflamed.

These sinuses are often long and tortuous. They wind along and around the muscles, the pus finding its way along the lines of least resistance in the intermuscular planes of areolar tissue, the external opening being often situated at a considerable distance, perhaps many inches, from the diseased bone. The difficulty of draining these long sinuses often leads to the accumulation of septic pus, at a certain degree of pressure in the deeper parts, in consequence of which the suppuration may be maintained almost indefinitely, the patient finally dying of exhaustion, chronic septic poisoning, or albumenoid degeneration of internal organs.

In the earlier stages tuberculous disease of bone is not necessarily associated with any constitutional disturbance, although not unfrequently the patient is already the subject of the characteristic symptoms of the strumous diathesis. In many instances, however, even though the local disease be very limited, a definite nocturnal elevation of temperature will be met with, and may be a valuable aid to the correct diagnosis of a doubtful case.

On naked-eye examination of the bone from a case of tuberculous caries it will be found to be much more porous and fragile than natural, the cancelli being thinned and the spaces enlarged. Here and there cavities will be seen where the cancelli have been completely destroyed and the spaces have coalesced. In these cavities loose pieces of dead bone may be lying. A fresh specimen shows the following appearances proceeding from the circumference to the centre of the carious patch. The earliest morbid change is increased vascularity of the medullary tissue, which is redder than natural; the next change observed is that the normal fatty or dark red semifluid marrow has been replaced by pink gelatinous granulation tissue, and that the cancelli are becoming thinned. Nearer the centre the bony cancelli entirely disappear, and the new tissue becomes opaque and pale yellow from fatty degeneration. In the centre it may form a caseous mass, softening in parts into a thick, curdy, puriform fluid. Grey granulations are seldom to be recognized. If they are seen they

Fig. 513.—Tuberculous Disease of Radius and of the Index Finger.

are more likely to be found near the circumference where they have not yet been concealed by the further inflammatory changes around them. Caries necrotica presents the same appearances, with the addition of fragments of dead bone, mixed with the degenerating inflammatory products. If these are decomposing they will be black or grey in colour; if not, they are white. If the process have been very chronic, small patches of opaque white bone may be found, in which calcification has taken place in the inflammatory products filling the cancelli.

**Treatment.**—The constitutional treatment of cases of tuberculous bone disease is often of the first importance.

In many cases, especially in young subjects, perfect rest of the diseased part, combined with means calculated to improve the general health, will be sufficient to effect a cure. Hence it is well not to be in too great a hurry to interfere, by operative means, especially in the case of the small bones of children. I have often seen cases, especially of caries of the bones of the hands and feet, in which an operation for the removal of the diseased bone was apparently indispensable, recover spontaneously on change of air and attention to the general health of the child; the disintegrated particles of the diseased bone being eliminated piecemeal.

In the earlier stages of caries, should there be any acute inflammatory symptoms, measures should be taken, by means of appropriate local and constitutional antiphlogistics, to subdue the activity and limit the extension of the disease; and when this has fallen into a chronic state, constitutional alteratives should be employed. Amongst these, cod-liver oil, the iodides, and change of air, more especially to the sea-side when the patient is young, should hold the first place. Counter-irritation is of little avail in these cases in arresting the progress of the disease. By means of blisters or iodine, thickening of the periosteum and of the soft structures covering the diseased patch of bone may be lessened, and pain subdued; but the real progress of the osseous disease cannot, I think, be influenced by such means when once it has passed the earliest stage.

In the majority of cases, however, operative interference sooner or later becomes necessary, and should in no case be delayed when definite signs of a chronic abscess are present. Earlier than this it may often be necessary to explore the bone when there is marked painful enlargement which is not relieved by other treatment.

**Operations.**—In all cases the part should, if possible, be rendered bloodless by Esmarch's method, as the operator will then be able to see what he is doing, instead of working in a deep hole filled with blood. In the case of a tuberculous abscess under the periosteum, a free incision should be made and the pus and granulation tissue cleanly removed with a sharp spoon. The surface of the bone is often carious and will require scraping. The superficial wound may be closed with sutures or left freely open and a lasting gauze and wool dressing applied. In tuberculous osteomyelitis good results will often follow a thorough scraping away of the diseased medulla; in some cases, however excision of the affected bone or amputation will be required.

In the treatment of tuberculous disease of cancellous bone the operations practised are of four kinds: Removal of the Diseased Portion of Bone; Excision of the Carious Articular End; Resection of the whole of the Bone affected; or Amputation of the Whole Limb.

Before proceeding to the *Removal of the Carious Portion of the Bone* the limb should be rendered bloodless by Esmarch's method. The diseased portion of bone is then exposed by a suitable incision through the soft parts. The carious bone is best removed in most cases by means of a Volkmann's sharp spoon, or a gouge. As a rule, the gouge is only necessary to remove the superficial parts of the bone in central caries. For cleaning out the actual cavity the spoon is much better, as it is less likely to injure surrounding parts, and by using instruments of various shapes every part of the cavity may be cleaned in the same way as a dentist cleans a carious tooth. In some cases it may be necessary to use a small trephine to open up the cavity in the affected bone. I have found the *gouge-forceps* (Fig. 521) very useful in clearing away angular fragments and projections of bone. In some cases Marshall's *osteotrite* (Fig. 514) will be found a very serviceable instrument, clearing away the softened carious bone without risk to the surrounding healthy structures.

In removing carious bone with these instruments, the Surgeon may sometimes be at a loss to know when he has cut away enough. In this he may generally be guided by the difference in texture between the diseased and healthy bone; the former cutting soft and gritty, readily yielding before the instrument, whilst the latter is hard and resistant; so that, when all the disease is removed, the walls of the cavity left will be felt to be compact and smooth. In some cases, the healthy bone may have been softened by inflammation; should there be any doubt as to the condition of what has been gouged out, the question may be settled by putting the detritus into water, when, if carious, it will become either white or black, whereas if healthy, but inflamed, it will preserve its red tint. In operating on young children especially, it is important not to use too much force, lest the inflamed, but otherwise healthy though somewhat softened bone, be cut away together with that affected by caries. After the operation the cavity must be carefully cleaned to remove any detritus or loose fragments that may be left behind. This is best done by means of pieces of sponge held in a pair of forcipressure forceps. The sponges should be moistened with chloride of zinc (gr. xl. to ʒj) or liquefied carbolic acid so as to disinfect the wound thoroughly. All unhealthy granulation tissue lining the sinuses should be scraped away with the sharp spoon. A few grains of iodoform may be introduced into the cavity and a small piece of green oiled silk may be put on the wounds to prevent scabbing. Unless the wound is large it may be left open to heal by granulation. In large wounds a catgut stitch may be put in at each end. Drainage-tubes should be avoided if possible. The best dressing is iodoform or salicylic wool, applied so as to form a covering about an inch and a half to two inches thick over the wound, and extending at least six inches on each side of it. This may be changed at the end of a week for the purpose of removing the drainage-tube if one has been inserted. A similar dressing is then applied, and if the part affected is near a joint, a plaster-of-Paris bandage may be put over it and left on for a month or six weeks, unless some discharge shows out from beneath it, or the patient com-

Fig. 514.—Marshall's Osteotrite

plaints of pain, or suffers from febrile disturbance. A considerable number of cases have been treated in this way in University College Hospital with the best results. In a large proportion the wound has been found completely healed when the second dressing was removed. If the cavity be of very large size, more frequent dressings may be necessary. If the materials for this dressing are not at hand the wound may be dressed with carbolic oil, glycerine and carbolic acid, terebene and oil, or any other efficient antiseptic application.

In cases treated in this way the cavity in the bone fills with aseptic blood clot into which granulation tissue sprouts from the surrounding bone. It has been recommended to pack the cavity with some firmer material which may take the place of the blood-clot: for this purpose, Hamilton of Aberdeen has employed aseptic sponge, and Senn of Chicago has used decalcified bone which has been kept in a 1 in 500 solution of corrosive sublimate in alcohol. It is doubtful, however, whether these materials have any real advantage over aseptic blood-clot.

Instead of removing the affected bone by means of instruments, Pollock has recommended that it should be dissolved by the application of a strong solution of sulphuric acid. The treatment is carried out as follows: the carious surface or cavity being exposed as before described, a solution of equal parts of strong sulphuric acid and water is applied by means of a glass brush or rod and this may be repeated daily till the whole surface is quite free from diseased bone. In deep cavities a piece of lint soaked in a weaker solution (one part of the acid to five or six of water) may be stuffed in and left for two or three days. The slough resulting may in a day or two more be peeled off with forceps and the application repeated if any diseased bone can still be seen. The treatment is said to be efficacious, and the pain accompanying it is not severe.

When tuberculous disease affects the articular ends of the bones, as those that enter into the formation of the elbow or shoulder-joints, it may be situated as not to admit of removal in the way just indicated, but to require *Excision* of the diseased articulation; this operation will be considered in subsequent Chapter. When a bone is so extensively diseased that neither of the preceding plans can be carried out successfully, it becomes necessary to perform either the *Resection* of the whole of the bone, if it be of small size, or *Amputation* of the limb, if of greater magnitude or if the neighbouring joints be extensively affected. Thus, for instance, resection of the os calcis may be required for caries of that bone; while, if the whole of the tarsus be affected, amputation is the only resource.

#### NECROSIS.

**Necrosis** is not a disease but may be the result of any pathological condition of a bone by which the vitality of a more or less extensive portion is destroyed. Caries may be regarded as a condition closely analogous to ulceration of the soft tissues; whilst necrosis must be looked upon as identical with gangrene. Whilst caries, however, chiefly affects the cancellous structure, necrosis is more with in the compact tissue of bone, and occurs far more frequently in the shafts than in the articular ends of the long bones. It is, however, an error to suppose that the cancellous structure is exempt from necrosis: thus in the head of the tibia, or in the os calcis, small masses of necrosed bone are not

unfrequently found lying in the interior of carious or suppurating cavities. Different bones are affected by necrosis with varying degrees of frequency. The tibia at its anterior part is most frequently diseased; the femur in its lower third is also very commonly affected. The lower end of the humerus is not so often necrosed; but not uncommonly the phalanges of the fingers from whitlow, the skull from syphilis, the lower jaw from the emanations evolved in the manufacture of phosphorus matches, and the clavicle and ulna from injury or constitutional causes, are found affected by necrosis.

**Causes.**—The causes of necrosis are very various. We have just seen that it is *Predisposed* to by the structure of particular parts of bone, and is more frequent in some bones than in others. Among the constitutional conditions which predispose to it, we must rank in the first line scrofula and syphilis.

The *Essential* causes of necrosis act locally and may primarily affect the periosteum, the osseous tissue itself, or the medulla.

**Affections of Periosteum.**—An injury to the bone may cause necrosis by stripping off the periosteum; but, though the bone thus injured often loses its vitality, yet, if the membrane be replaced, its life may be preserved, and even when the bone is exposed, adhesions may take place between it and the neighbouring soft parts, or granulations may be thrown out by its surface, which eventually form another periosteum. Necrosis also frequently occurs as the result of the detachment and denudation of a portion of bone in cases of bad compound fracture. Before the age of puberty almost all cases of extensive necrosis of the shafts of long bones are the result of acute diffuse periostitis or acute necrosis (see p. 277). Allied to this variety are those cases in which necrosis follows acute specifics, more particularly typhoid and scarlet fevers. Scarlet fever especially is apt to be followed by pains in the leg and about the knee, which at first appear to be of a rheumatic character, but which speedily run into abscess and are attended with all the symptoms of the most acute form of necrosis.

Sometimes the death of bone results from the extension of inflammation to it from the neighbouring tissues, as in some cases of whitlow, or from the destruction of its periosteum by a neighbouring abscess.

Two of the varieties of syphilitic necrosis must be included under this heading: in one form the periosteum is destroyed by the extension of superficial ulceration to it; in another form necrosis results from the formation of subperiosteal gummata, which finally soften and thus cut off a piece of bone from its vascular supply. The growth of a tumour beneath the periosteum may sometimes cause necrosis in a similar way.

**Affections of the osseous tissue.**—Of these the condition which most commonly leads to necrosis is chronic osteoplastic osteitis with gradual cutting off of the blood supply of the affected area by obliteration of the Haversian canals (p. 262). In this way a third variety of syphilitic necrosis is produced. In cancellous bone necrosis is usually associated with caries, and most commonly arises from chronic inflammation, usually tuberculous, accompanied by caseation of the inflammatory products by which the vascular supply of the affected area is cut off.

The necrosis of the lower jaw which occasionally occurs amongst workers with phosphorus probably results from the direct action of the acrid fumes gaining access to the bone through carious teeth.

*Affections of the medulla.*—Acute osteomyelitis following injuries of bone is a not uncommon cause of necrosis, especially after amputations (p. 262), or should the condition arise without injury (p. 263) the same result takes place. Necrosis may also be caused by tuberculous osteomyelitis (p. 264).

In some cases necrosis occurs in old people without any evident cause, being then apparently simply the result of old age. This I have seen occur in the lower ends of the humerus and tibia, giving rise to rapid and usually fatal disorganization of the neighbouring joints, or to death from exhaustion after profuse suppuration. This *Senile Necrosis* may be looked upon as the counterpart in the bone of senile sloughing or gangrene in the soft parts.

**Characters.**—In whatever way it originates, necrosis may affect the outer laminae only of the bone, when it may be called *peripheral*; or the innermost layers that surround the medullary canal may perish, and then it may be termed *central*; or the whole thickness of a shaft, or of the substance of a short bone, may lose its vitality, and the necrosis is then spoken of as *total*. The necrosed portion of bone, called the **Sequestrum**, presents peculiar characters, by which its nature may at once be recognized. It is of a dirty yellowish-white colour, and has a dull opaque look, and, after exposure to the air, it gradually acquires a deep brown or black tint; the margins are ragged, and more or less spiculated, and the free surface is tolerably smooth, but its attached surface is very irregular, rough, and uneven, presenting an eroded or worm-eaten appearance. This eroded appearance is very marked in sequestra that form in the interior of the terminal end of the femur in a thigh-stump after amputation, and is well illustrated by Fig. 29, where the lower smooth part is composed of the whole thickness of the bone, whilst the upper rough and spiculated portions consist of the central layers of bone separated from the outer layer, and hence their eroded external surface. When the sequestrum forms in the cancellous tissue, it is usually of a blackish-grey colour, and irregular or ovoid in shape.

When the necrosis has been the result of an acute inflammatory process, as osteomyelitis or infective periostitis, the bony tissue of which it is composed has exactly the appearance of a corresponding piece of healthy bone macerated after death. On the other hand, when the death of a piece of bone has been a complication arising during some chronic inflammatory process, the sequestrum bears evidence of the previous disease upon it. Thus, if it result from osteoplastic osteitis, it is denser than natural; if from rarefactive osteitis, as is commonly the case in necrosis of the cancellous tissue, it is lighter and more porous than the normal structure, and often eaten out into irregular cavities, or it may present patches of calcification in the cancellous spaces.

**Symptoms.**—The symptoms of necrosis are divisible into three distinct periods. In the first they are those of the disease in consequence of which the death of the portion of bone has taken place, being acute in acute diffuse periostitis or osteomyelitis, chronic in chronic periostitis and osteitis, tuberculous caries, or in syphilitic caries, periostitis or subperiosteal gummata. In the second period the primary disease having ceased, the process of separation of the dead bone from the living takes place with the formation of a suppurating layer of granulation tissue at the expense of the latter, and simultaneously new bone is formed from the periosteum to maintain the rigidity of the part.

when the dead portion becomes loose. In the third period, the sequestrum having been expelled or removed, the final processes of repair take place by which the restoration to the proper size and shape of the bone is effected. The particular character of the symptoms depends, however, not only on the stage and cause, but also in a great measure on the seat and the extent of the necrosis. As already stated, the sequestrum may be peripheral, central, or total, perhaps involving the whole thickness of the shaft.

The acute diseases causing necrosis have already been sufficiently described, but a few words are required on some of the chronic forms.

When the necrosis is associated with caries, as in caries necrotica, the symptoms are those already described as occurring in that condition, pain like that of rheumatism, and tenderness with gradual enlargement of the affected bone. At a later period chronic suppuration takes place, and the abscess at last points beneath the skin. When this is opened a probe will pass into the carious cavity in which the sequestrum is lying. When the sequestrum is small and central, it may become enclosed with a small quantity of cheesy pus in a dense wall of solid bone. The symptoms are then those of chronic abscess.

Extensive necrosis may occasionally take place without the formation of a drop of pus. Cases of this kind have been described by Paget under the name of *quiet necrosis*, and by Marrant Baker as *necrosis without suppuration*. The symptoms are those of chronic osteitis and periostitis (p. 269), and the diagnosis can be made only when, all means of treatment having failed, trephining of the bone is undertaken for the relief of the pain. In Baker's case the enlargement exactly resembled a tumour, and as spontaneous fracture finally took place, there seemed no doubt as to the nature of the disease. The real condition was discovered only after amputation at the hip-joint. In these cases the necrosis is due to arrest of the circulation by osteoplastic periostitis obliterating the Haversian canals, and the part necrosed is always the central portion of the compact tissue of the shaft.

Another course taken by necrosis, especially when it follows fevers, may best be illustrated by briefly describing three typical cases. The first was that of a girl aged 14, who complained of persistent pain in the buttock after an attack of rheumatic fever. A hard brawny swelling gradually formed during the following year. It was aspirated but nothing was found, and fears were entertained that it might be a sarcoma. Some weeks after a few drops of pus escaped from the puncture, and on dilating the opening a small sequestrum, about the size of a thumb-nail, was found detached from the side of the pelvis. The second was that of a man aged about 35, who complained of a slowly-growing tumour, about 2½ inches in diameter, under the right nipple, that had appeared some months after typhoid fever. He was sent into University College Hospital as a case of scirrhus of the male breast. There was one small enlarged gland in the axilla, and there seemed no doubt about the diagnosis, but to avoid any possibility of error a deep incision was made into the growth, which grated under the knife, and felt and looked like scirrhus. It was accordingly removed, when a small cavity half an inch in diameter was found beneath, containing some caseating granulation tissue; the finger passed from this through the pectoralis major to a small sequestrum on the fifth rib. The third case was that of a girl, aged about 14, who was sent into the hospital for a tumour, supposed to be an enchondroma, just below the crest of the ilium. On cutting down on this, it proved to be a chronic abscess with exceedingly

thick walls, containing a sequestrum about the size of a split pea which had been separated from the ilium. She had recently recovered from typhoid fever.

**Separation of the Dead Bone and Formation of Provisional New Bone.**—The separation of the dead bone, or its *Exfoliation*, is carried out by a process precisely similar to the mode in which a slough in soft tissues is thrown off, the only difference being the time required. Rarefying osteitis is set up in the living tissue where it meets the dead. The details of this process have already been described (Vol. I., p. 271). As the result of it a narrow zone of the living bone is destroyed, and its place occupied by soft vascular granulation tissue. This process goes on most rapidly in the most vascular parts: thus we see the granulation layer first completely formed near the periosteum and medullary canal, and gradually advancing from these points till the dead bone is completely separated from the living. If a bone in which a sequestrum is partly separated be macerated so as to destroy the granulation tissue, a groove about one-twentieth to a quarter of an inch wide will be seen. On the living side of this the bone is porous and its Haversian canals enlarged and gradually coalescing. On the dead side the bone retains its normal compact structure. The line between the dead and the living tissue is always extremely irregular. The granulation tissue in contact with the dead bone yields a more or less abundant supply of pus, which, according to B. Cooper, may contain as much as  $2\frac{1}{2}$  per cent. of phosphate of lime. When the separation is complete the dead bone lies closely surrounded by vascular granulation tissue, and bathed in a certain quantity of pus. If decomposition occur the pus will be increased in quantity in consequence of the irritation of the granulation tissue by the septic products.

When once the dead bone has been detached by the formation of this line of separation, nature takes steps for its ultimate removal from the body. There is no evidence that it, in any circumstances, undergoes absorption to any appreciable extent; although, as Paget and Billroth remark, that portion which remains in contact with proliferating granulations may undergo a certain amount of diminution. That this may be so is rendered more probable by the fact that the ivory pegs used in the treatment of ununited fracture have been found to be partly absorbed after some weeks. The absorption of the margin of the living bone, in the formation of the line of separation, explains the fact that the sequestrum will always be found to be of much smaller size than the cavity in which it is lodged. The ultimate expulsion of the loosened sequestrum is effected by the growth of the granulations below it pushing it off the surface, or out of the cavity in which it lies. When the necrosed bone is *peripheral*, it will be readily thrown off in this way, although it may for a time be fixed and entangled amongst the granulations. When the sequestrum is *invaginated* within new or old bone, the process of elimination is necessarily very slow, and may be difficult or impossible without surgical aid.

The time required for the separation of dead bone varies greatly. When it is superficial and small in size, a few weeks may suffice; but when the long or flat bones, as the femur, the scapula, or the ilium, are affected, the process extends over several years, and may terminate in the death of the patient from exhaustion before it is concluded; the constitution being worn out by hectic induced by profuse suppuration. Or the disease may fall into a chronic state,

the limb becoming rigid, and the tissues much indurated, with sinuses leading down to exposed but attached bone, and thus being a source of constant annoyance and suffering to the patient.

During the process of separation of a piece of dead bone and after the abscess first formed has burst, sinuses are left leading to the sequestrum through which pus is constantly discharged. The skin is unaltered in appearance, unless the sequestrum be seated in a superficial bone, when it is usually rigid and often red, smooth and shining. The soft parts surrounding the bone are always more or less indurated. The openings of sinuses leading to dead bone are usually surrounded by an elevated ring of granulation tissue, often thinly covered by epithelium, the orifice presenting a peculiar appearance, which the older Surgeons compared to the cloacal aperture of a fowl.

**Reparative Process.**—The reparative process adopted by nature for the restoration of the integrity of the bone, a portion of which has necrosed, varies according to the extent of the loss of substance. When the outer lamellæ alone are necrosed, new bone is deposited by the surrounding periosteum, and the depression that has formed on the surface of the old bone is filled up by granulation tissue, which ultimately ossifies. If the whole of the inner lamellæ of the shaft die, constituting *central necrosis*, the outer layers of bone become greatly consolidated and thickened by osseous matter deposited from the periosteum; in which, in the majority of cases, the circular or oval apertures termed *Cloaca* are left for the escape of pus and the ultimate extrusion of the sequestrum (Fig. 515). In cases of "necrosis without suppuration" (p. 289), however, no cloacæ form, the dead bone continuing to be encased in the thickened outer layers. When the whole of a shaft dies, the reproduction takes place from various sources, principally from the periosteum, which is, indeed, essentially the organ of reproduction of bone; this becomes thickened and vascular. That the periosteum takes the principal share in the reproduction is evident from the fact that, where it is deficient or has been destroyed, apertures are left in the case of new bone; and if it be removed altogether, osseous tissue is either not formed at all, or most sparingly by the contiguous old bone, or by the epiphyses. The soft tissues, also, of the limb generally, if thick, as in the thigh, contribute to the formation of granulation tissue, which gradually ossifies and so tends to strengthen the new case; and, lastly, the articular ends of the old bone, still preserving their vitality, constitute most important agents in the reparative process, becoming consolidated firmly to the new shaft that is formed. The importance of the periosteum as the organ of regeneration of bone after the removal of the osseous structures, whether experimentally or surgically by resection, or by necrosis, has been conclusively demonstrated by Ollier of Lyons. This surgeon has shown by many ingenious experiments, that in the lower animals reproduction of a whole bone may take place, as in the case of the radius in rabbits and pigeons, after it has been

Fig. 515. — Central Necrosis. New Bone with Cloacæ; included Sequestrum.

removed from within the periosteum ; and that, if the periosteum be dissected off in slips, and twisted here and there between the muscles of the limb, new bone of various shapes may be formed on and by this partially detached membrane. Ollier has further shown that, although in man, after operations and disease, new bone may be formed by the contiguous osseous tissue, and even by the neighbouring soft parts, yet the periosteum is essentially the organ of the regeneration of bone ; thus confirming, by new and ingenious experiments, and by additional observations, the views that have just been expressed. The whole of a necrosed bone may, after separation, be reproduced by the periosteum. This is admirably illustrated by the annexed drawing, taken from the photograph of a preparation in the museum of the late J. Wood of New York. The whole of the inferior maxilla had separated as the result of phosphorus disease ; the patient, a girl, lived for three years, the lower jaw having been reproduced as a perfect ring of bone, as represented in Fig. 516.

Fig. 516.—Reproduction of Lower Jaw after Phosphorus Necrosis.

Thus it will be seen that the new bone is formed by the vascular and healthy tissues generally that surround the seat of disease, though in this reparative process the periosteum takes the chief share, the epiphyses and old bone the next, and the areolar tissue of the limb a very secondary part if any. In acute necrosis, repair commences as soon as the intensity of the inflammation has been reduced by the escape of pus through the incisions. In a few days

the swollen and thickened periosteum will be found to be lined with scales of new bone, the first step towards the reproduction of the shaft.

The new bone deposited on those parts of the surface of the shaft from which a scale of the old osseous tissue has been separated, or enveloping the sequestrum when the whole thickness of the shaft becomes necrosed, is at first rough, porous, cancellated, and very vascular ; after a time it gradually becomes harder and more compact. The case of new bone, which necessarily exceeds in circumference the old bone, as this is included within it, gradually contracts both in texture and in size, becoming firmer and smaller after the removal of the sequestrum ; and, the cloacæ closing as soon as all dead bone has been extruded, it eventually acquires the proper size and shape of the bone ; the medullary canal even becoming more or less perfectly restored. In this way, restoration of the whole of the shaft of many of the long bones, such as those of the arm, forearm, and leg, will take place, provided always the epiphyses have been left untouched by disease. If one or other of these has been destroyed, all power of repair seems to be lost.

The new bone usually forms with such rapidity that the shell surrounding the sequestrum, or the *involutum* as it is termed, is sufficiently strong to support the limb by the time the dead bone is loose.

In cases of acute necrosis, in which amputation has been performed but a few weeks after the setting in of the disease, a thick layer of new bone will sometimes be found under the periosteum ; but in some instances, when the whole of a bone is necrosed, the new case is not completed, or has not become attached to —

articular ends before these are separated from the shaft. In other cases, though complete, it has not sufficient strength to resist the contractions of the muscles of the limb; under these circumstances, it may spontaneously fracture—an accident that I have seen happen both in the femur and the tibia—or may become shortened or bent. In other instances, again, when the periosteum has been lost by sloughing, new bone does not form (Fig. 517); but as the sequestrum separates, the limb becomes shortened, loose, deformed, and useless.

**Treatment.**—In the treatment of necrosis, the indications to be accomplished are sufficiently simple, though the mode in which they have to be carried out often requires much patience and skill on the part of the Surgeon. In those cases in which the bone is perishing from some chronic progressive disease, as chronic osteitis and periostitis with obliteration of the Haversian canals, or when it is associated with caries, the first point is to remove, if possible, any constitutional or local condition which tends to keep up the disease. Thus, for instance, if it appear to be the result of syphilis, this condition must be corrected. So, again, if it arise in the lower jaw from the fumes of phosphorus, the patient must necessarily be removed from their influence. If it be threatened in consequence of denudation of bone, the best mode of prevention will be to lay down flaps of integument and so to cover the exposed surface. Abscesses should be opened as soon as recognized. In cases of acute infective periostitis the extent of the necrosis is very materially limited by free and early incisions and the use of antiseptics, and in this way the separation of the epiphyses can often be prevented, and the danger of death from exhaustion or pyæmia avoided.

**Removal of the Sequestrum.**—When all that is possible has been done to arrest the morbid condition to which the necrosis is due, the separation of the sequestrum should be left as much as possible to the unaided efforts of nature. The less the Surgeon interferes with this part of the process the better; for, as has justly been observed by Wedemeyer, the boundaries of the necrosis are known to Nature only, and the Surgeon will most probably either not reach, or will pass altogether beyond them. Here much patience will be required for many weeks or months: and the utmost the Surgeon can do is to attend to the state of the patient's health, treating him carefully upon general principles, removing inflammatory mischief by appropriate means, opening abscesses as they form in the limb, limiting or preventing the decomposition of the discharges by antiseptic applications, and at a later period, keeping up the patient's strength by good diet, tonics, and general treatment, calculated to support him against the depressing and wasting influence of continued suppuration.

As soon as a sequestrum has been detached from the adjacent or underlying bone the Surgeon must proceed to its removal. In most cases it is sufficiently easy, when the necrosis is superficial, to ascertain that this separation has taken place, as the flat end of a probe may be pushed under the edge of the detached lamina. When, however, the sequestrum is deeply seated, it is not always so

Fig. 517. — Acute Necrosis of Tibia. Deficient Formation of New Bone.

easy to be sure that the separation has occurred; though, in the majority of cases, the introduction of a probe through one of the fistulous openings leading to the necrosed bone, and firm pressure made upon the latter, will enable the Surgeon to determine this. In other cases, however, the sequestrum, though completely free from all osseous connexions, still continues to be fixed by the pressure of the surrounding granulations, and by the extension of its spicula into the corresponding cavities of the new osseous case. This especially happens when the sequestrum is central and invaginated, and the cloacæ leading to it are so small that but a limited portion of it is exposed. Here a more careful examination will be required; and its looseness may sometimes be determined by pressing upon it with a probe in a kind of jerking manner, or by introducing two probes through different cloacæ, at some distance from one another, and alternately bearing upon the exposed bone with one or other of them. Then, again, if the sound elicited by striking the end of the probe against the sequestrum be a peculiarly hollow one, the detachment of the bone may be suspected. The duration of the case, also, will probably throw some light upon the probable state of things inside the involucrum.

The separation of the sequestrum having been ascertained, the Surgeon must adopt measures for its extraction. The part should first be rendered bloodless by Esmarch's apparatus if the disease is situated in a limb. If the necrosis be *peripheral*, all that is necessary is to make an incision down to it through the soft parts, either by directly cutting upon it or by slitting up sinuses with a probe-pointed bistoury, and then to remove it with a pair of forceps, or to tilt it off the bed of granulations on which it is lying, by introducing the end of an elevator beneath its edge.

When the necrosis is *central*, the sequestrum being embedded in a new case or covered in by old bone, the operative procedures for its removal are of a more complicated character. The difficulties here consist in some cases in the depth from the surface, and in the obstacle offered to its passage by the soft parts; in others, in the length and magnitude of the sequestrum in proportion to the small size of the cloacæ, and in the manner in which it lies in a direction parallel to these openings. In cutting down upon the bone, the Surgeon must be guided by the direction and course of the fistulous tracks that lead to the principal apertures in the new case, the incision being placed in the axis of the limb, and carefully directed away from the large blood-vessels and nerves. If the part has not been rendered bloodless, however, the hæmorrhage is somewhat abundant, in consequence of the injected state of the tissues furnishing a copious supply of blood, and their rigid condition preventing retraction of the vessels; this, however, may be arrested by a tourniquet, or by the pressure of an assistant's fingers, and will soon gradually cease of itself. The bone having been freely exposed, it will sometimes be found that the cloacæ are of sufficient size to allow the ready extraction of the sequestrum. But in the majority of cases, this cannot be done at once, and the apertures must be enlarged, either with the chisel or the trephine, according to the density of the new case, and the amount of room required. Occasionally when two cloacæ are close to one another, the intervening bridge of bone may very conveniently be removed by means of cutting forceps, of different shapes (as in Figs. 518, 519, and 520), or by means of a Hey's or a straight narrow saw having a movable back to stiffen the blade (Fig. 522), and space thus given for the extraction of the sequestrum. Very convenient forceps for this purpose are those

represented in Fig. 521. They are made with gouge ends, and hence may be termed *gouge-forceps*. I have found them extremely serviceable in many operations upon the bones. Care, however, should be taken not to remove more of the new case than is absolutely necessary, lest the ultimate soundness of the limb be endangered. In necrosis of the lower end of the femur the bone surrounding the sequestrum is often so peculiarly dense that it can be cut away so as to expose the dead bone only by the means of a chisel and mallet, used with considerable force. For the extraction of the sequestrum, the most convenient instrument is a pair of strong necrosis-forceps, well roughened at their ex-

Fig. 518.

Fig. 523.—Sequestrum Forceps.

trinity, and straight or bent as the case may require (Fig. 523). Occasionally the sequestrum is so shaped and placed that it cannot be seized with this instrument; in these circumstances it will be useful to drive a screw-probe into it, by which it may either be extracted, or so fixed as to admit of seizure and removal by the forceps. If the sequestrum be too large to be removed entire through the cloacæ, it may perhaps best be extracted piecemeal, having been previously divided by passing the points of narrow but strong cutting forceps into the interior of the bone.

After the removal of the sequestrum, a smooth hollow cavity will be left in the new case, from the bottom and sides of which blood usually wells up freely, issuing abundantly from the vascular bone, and from the granulations lining

its interior. Should this hæmorrhage be at all troublesome, elevation of the limb and pressure will always arrest it without difficulty. In the subsequent treatment the chief trouble arises from the accumulation of discharges in the cavity from which the bone has been removed, where they are prone to become excessively foul. To prevent this the cavity should be washed out with chloride of zinc solution (gr. xl. to 3j.) immediately after the operation, and some crystalline iodoform sprinkled in it. It may then be dressed with salicylic or iodoform wool. In this way it can often very soon be brought into a condition to require dressing only about once a week. If these dressings are not at hand, carbolic oil, terebene and oil, or glycerine and carbolic acid, may be applied, and the wound well syringed with Condy's fluid. If the sequestrum have been a long one, and have involved the greater part of the shaft of the bone, it may happen that the new case has not sufficient strength to maintain the limb of its proper length and shape, and that it will bend or break under the action of the forces and weight to which it is subjected. In order to prevent this accident, it will be necessary to put it up in light splints, or in a starched bandage. After the removal of the dead bone, the sinuses will speedily close, and the limb eventually regain its normal size and shape.

**Amputation.**—If the necrosed bone be so situated that it cannot be removed, occupying too great an extent and continuing to be firmly fixed; and if at the same time the patient's health have been lowered by constant discharge, and symptoms of hectic come on; or if the limb have generally been greatly disorganized by the morbid processes going on in it, recourse must be had to amputation as a last resource. It is especially in the lower third of the thigh-bone that these severe forms of necrosis necessitating amputation of the limb occur. When necrosis affects the flat posterior surface of this bone above the condyles, a special source of danger occurs in the possibility of the sequestrum causing ulceration or wound of the popliteal artery. In cases of this kind, suddenly fatal hæmorrhage might occur. Should the hæmorrhage, though abundant, not be fatal, what course should the Surgeon adopt in such cases? Should he attempt to ligature the vessel, or should he amputate the limb? The line of practice must, I think, be determined by the condition of the limb itself and by the state of the patient's health. If both these be tolerably good, the limb not too much disorganized, and the powers of the system not too much reduced by hectic, an attempt might be made, by slitting up the sinuses, to expose and secure the popliteal artery at the seat of injury in it, and, by ligaturing it, to save life and limb. But should this attempt fail, as I have known happen, or should it not be thought prudent to make it, owing to the low state of the patient's strength, or the disorganized condition of the limb, amputation must be done without delay. Necrosis of the tibia requiring amputation is rarely met with, except as the result of bad compound fractures, or of other serious injuries. In acute necrosis of the lower end of the thigh, or of the shaft of the tibia involving the contiguous joints, and attended with deep and extensive abscess of the limb, amputation is imperative.

**Resection** of the whole of the necrosed bone may advantageously be performed in such cases as those of the metacarpal and metatarsal bones, or in those of the forearm or leg, where sufficient stability of limb is secured by the remaining bone or bones to leave a useful member. The diseased bone may be thus removed in necrosis of the ungual phalanx occurring from whitlow,

where, by the excision of the dead bone, the end of the finger may be preserved ; also in necrosis of some of the metatarsal and tarsal bones, or those of the forearm, and the fibula. Subperiosteal resection in cases of acute necrosis has already been alluded to (p. 280).

It will be convenient to consider here the chief varieties of necrosis and caries as they affect the cranial bones, sternum and ribs, leaving the consideration of the bones of the extremities and of the spine for subsequent chapters.

**CRANIAL BONES.**—Necrosis and septic osteomyelitis of the bones of the skull following injury have already been considered (Vol. I., p. 718). Necrosis and caries may also arise as the result of syphilis or tubercle.

**Syphilis.**—In considering the syphilitic lesions of bones we have seen that the flat bones of the vault of the skull are frequently affected, and as the result of the breaking down of a subperiosteal gumma extensive caries or necrosis may occur. The frontal bone is most frequently affected, and in the case of any of the bones of the vault, different degrees of necrosis may be met with.

In one form, the outer table alone is affected ; this perishes, separates, and exfoliates, granulations spring up from the outer surface of the inner table, and a process of repair is thus established. In the second form of the disease, the whole thickness of the skull necroses, separates from the dura mater and surrounding healthy bone in the usual way, and may be detached in large irregularly shaped pieces, sometimes of large size, occupying several square inches. In the third form, the necrosis is hard, dry, rough, and pitted and worm-eaten, penetrating through the diploë to the inner table, separating very slowly, and lasting an indefinite period.

Syphilitic necrosis may also affect the bones of the base of the skull, especially the ethmoid and sphenoid. In the former case sequestra may sometimes be extracted through the nostrils, and in one extraordinary case under my care in University College Hospital, I removed through the mouth the whole body of the sphenoid bone. The patient, a man aged forty-three, had suffered from syphilis for fifteen years, and from disease of the bones of the nose and upper jaw for three years. The anterior part of the hard palate was destroyed, and it was through the fissure so formed that I removed the bone. The fragment included the sella Turcica, and the roots of the pterygoid processes, but the clinoid processes could not be recognised. The patient had suffered from no cerebral symptoms except occasional headache and some loss of memory. He made a good recovery.

The *Signs* of syphilitic necrosis of the cranial bones are very obvious. When the vault or forehead is affected, there is tenderness, with some puffiness, and gradual elevation of the scalp into an abscess. When this is opened, the necrosed bone may be felt or seen lying bare, at the bottom of a sinus or unhealed ulcer. When the sphenoid or the ethmoid is affected, deep pains in the head, persistent œdema of the eyelids, and fetid discharge from the nose, will reveal the nature and seat of the mischief.

The local *Treatment* of syphilitic necrosis and caries of the cranial bones will vary according to the nature and the seat of the disease. In the dry pitted variety, exposing and scraping the diseased osseous surface, or the application of a strong solution of sulphuric acid will often bring about a healthy action, provided the disease have not penetrated too deeply. Should there be reason to think that the inner table has been perforated, it will probably be safer to leave the case to the reparative processes of nature than to

trephine. If, however, the anterior wall of the frontal sinus be the seat of the disease, or if the supraorbital ridge be affected, the dry and rough bone may safely be removed, as I have twice had to do, by the application of the trephine in the first instance, and of the gouge in the other case. When exfoliating necrosis of the outer table, or of the whole thickness of the bone, affects the vault of the skull, the loosened plate may readily be lifted off its granulating bed by means of the elevator or forceps, after it has been fairly exposed.

**Tubercle.**—It has long been recognized that necrosis of the cranial bones not unfrequently occurs in strumous children, especially after measles and scarlet fever. It is now known that this is due to the deposit of tubercle in the bone. This may occur in the diploë or beneath the periosteum, and from the tendency which the disease has to destroy the whole thickness of the bone it has been spoken of by Volkmann as a "perforating necrosis." According to König the bones most frequently affected are the frontal, parietal, and temporal; the frontal bone in the region of the external angular process is the favourite seat of the disease. As a rule the lesion is single, but multiple foci may be present. A chronic abscess slowly forms over the diseased bone, and when this is opened the bone is found to be soft and carious and often perforated; small sequestra may be present. Tuberculous disease of the temporal bone may affect the tympanum or mastoid process. The *treatment* of these cases must be carried out on the same lines as that of tuberculous bone disease elsewhere—the abscesses being freely opened and the soft granulation tissue and carious bone removed with a sharp spoon. The disease may be extensive between the internal table and the dura mater, and great care must be taken that the latter be not injured.

**Results.**—In all forms of necrosis of the cranial bones, there is the special danger of extension of inflammation to the membranes of the brain, and the consequent occurrence of effusion within the skull, leading to convulsions, coma, and death. This danger is greatest when the petrous portion of the temporal bone is affected, as the dura mater is continued into some of the canals by which it is perforated. Cerebral complication is less likely to occur when the frontal bone is the seat of disease, more particularly the lower part of this bone, where, by the intervention of the frontal sinuses, the anterior wall is altogether carried away from the inner table, and from all dangerous proximity to the membranes of the brain.

**STERNUM.**—Necrosis and caries of the sternum are by no means uncommon, the former as the result of the breaking down of a subperiosteal gumma, the latter from tuberculous disease of the cancellous tissue. In either case any part of the bone may be affected, but the manubrium is most frequently the seat of disease. In cases of tuberculous caries the bone may be completely perforated, and a considerable abscess-cavity may exist on its posterior surface. Under these circumstances it may be necessary to gouge away the bone freely around the perforation. Extensive resections of the sternum have also been practised for tuberculous disease.

**Ribs.**—Tuberculous disease of the ribs is very common, and usually begins as a subperiosteal deposit. The bone may thus be superficially eroded or necrosis may occur; the inner surface of the rib is often chiefly affected. An abscess forms over the diseased bone and may communicate through an intercostal space with a considerable collection of pus between the ribs and the

pleura. The diagnosis from a localized empyema may thus sometimes be a matter of difficulty. In some cases the rib cartilage is necrosed, as the result of a tuberculous deposit beneath the perichondrium. The *treatment* consists in freely opening the abscesses and sinuses, and scraping or gouging the carious bone. In some cases it may be advisable to excise completely the affected portion. In these operations great care must be taken not to damage the pleura.

## CHAPTER XLVII.

## STRUCTURAL CHANGES IN BONE AND TUMOURS OF BONE.

## HYPERTROPHY OF BONE.

**True Hypertrophy of Bone**, that is to say, increase in size without alteration in form or structure, is very rare. It occurs as the result of excessive use, in common with the enlargement of the muscles inserted into it.

The term **Inflammatory Hypertrophy** is often applied to those chronic inflammatory processes which cause enlargement of a bone, diffused over a considerable part of its length. When the thickened bone is more spongy than natural, the change is termed *Spongy Hypertrophy*; when it is denser, *sclerosis*, or hardening of bone. Spongy hypertrophy occurs in its most marked form in the disease described by Paget as *osteitis deformans* (p. 309). Sclerosis is most commonly met with as the result of syphilis or after recovery from chronic osteitis and periostitis in scrofulous subjects. It may affect several bones at the same time; and, in the long bones, may lead to filling up of the medullary and Haversian canals with bony substance, with some thickening of the bone generally. This condition is not recognizable with certainty during life.

**Increase of Length of Bones.**—Allusion has already been made at p. 269 to the hypertrophy of bone which sometimes follows chronic osteitis. This increased growth of bone, as a result of morbid conditions, has been investigated by Stanley and Paget in this country, and by Langenbeck and others on the Continent. It has been observed in connexion with necrosis, chronic osteitis, and chronic abscess; and also with chronic hyperæmia of the soft parts of the limb. Langenbeck, from his observations, concludes that morbid changes which give rise to irritation and hyperæmia of the osseous tissue lead, as long as the growth of bone continues, to an increase both in length and in thickness; and that the increase of growth in length affects especially the diseased bones, but may also occur in a healthy bone of the same limb. Sometimes, as Paget has pointed out, the long existence of an ulcer of the integuments in a young person may produce thickening and elongation of the bone. When the femur undergoes elongation in this way, the inequality in length of the limb, unless the opposite limb be lengthened by artificial means, may lead to talipes of the foot of the lengthened limb or to lateral curvature of the spine. The tibia sometimes becomes elongated, while the fibula remains of its normal length; and in such cases the former bone becomes curved. The diagnosis of this condition from the curvature of rickets consists, according to Paget, in the marked elongation; in the absence of thickening of the ends of the bone, which are usually even more nearly equal in size to the shaft than in the natural state, on account of the thickening of the latter; and especially in the fact that "the rickety tibia

is compressed, usually curved inwards, its shaft is flattened laterally, and its margins are narrow and spinous; while, in the elongated tibia, the curve is usually directed forwards, the margins are broad and round, the surfaces are convex, and the compression or flattening, if there be any, is from before backwards."

**ATROPHY OF BONE.**—This term comprises two conditions: one in which the bone is wasted, and another in which an arrest of growth occurs.

**Atrophy** occurs, as a natural result, in old age; the change that takes place in the lower jaw being a familiar example. In other cases it is said to happen as a consequence of fracture; the nutrient artery of the bone having been torn across, and one of the fragments consequently receiving insufficient vascular supply. Atrophy of bone commonly occurs also from disease, as is the case in old dislocations. In atrophy, the bone becomes thinner, lighter, and more porous than natural; the compact structure disappearing until a mere paper-like layer may be left, and the cancellous becoming expanded, the spaces being filled with soft yellow fat. Atrophy of bones is common in general paralysis of the insane. It is often especially marked in the ribs, and is a common cause of fractures, occurring either spontaneously or during the restraint necessarily employed during a maniacal outbreak.

**Arrested Growth** of bones is an occasional consequence of disease. Its occurrence in rickets will presently be referred to. It may be a result of disease of the epiphyses and joints, or of the resection of the epiphyses in children, and may follow the formation of cicatrices after burns in the neighbourhood of joints. The effect of paralysis on the growth of bone varies according to the extent of the loss of nerve-power. It is common to see normal growth of the bones in limbs affected with infantile paralysis, in which the muscles are wasted; while in other cases it is materially impaired.

#### RICKETS.

**RICKETS** is a general disease, the most important manifestation of which is an imperfect development of the new tissue of growing bones. It occurs only in early childhood, most frequently appearing during the first or second year of life, though it has been observed as late as the ninth year, and is said occasionally to be congenital.

**Causes.**—Want of sufficient food and of fresh air, want of cleanliness and light, and all the unhealthy surroundings of the overcrowded poor of a large city, are the great causes of rickets. It is rarely met with amongst the wealthy classes, and in the country it is scarcely seen, even among the poor. Improper food is undoubtedly the essential cause of the disease. There is but one proper food for a child during the first nine months of its life, and that is the milk of a healthy woman. The ill-fed mothers amongst the working classes, exhausted as they often are by repeated child-bearing and unnaturally prolonged lactation, are very frequently unable to supply milk of a sufficiently nutritive quality, and thus, even when suckled, the child is but half-fed. Should it be brought up by hand, in order to save expense, flour, or various useless patent preparations of starch, are largely used in place of cow's milk.

The starchy materials in the food probably take no active part in the production of the disease, but replace those necessary constituents which the child is capable of digesting. It has indeed been suggested that rickets is caused by an excess of lactic acid resulting from fermentation of imperfectly digested starch; the lactic acid unites with the lime of the bones and converts it into a soluble salt. There is no evidence in favour of this view, and Cheadle has raised the serious objection that it would be inadequate to explain more than the bone changes of rickets, which must not be looked upon as the only result of the disease. Everything, indeed, suggests that the error of a diet which produces rickets is that it lacks some essential constituent and not that it contains any directly harmful substance. Cheadle is of opinion that this error consists chiefly in a deficiency of animal fats, aided perhaps by insufficiency of earthy phosphates and animal proteids. In support of this opinion he cites a case of most extreme rickets occurring in a child fed on skim milk, and also the beneficial effect of cod-liver oil. The cure of rickets in the lion cubs at the Zoological Gardens, which were fed only on horse-flesh, by giving them cod-liver oil and pounded bones with milk, is a remarkable instance of the part played by an improper diet in the production of the disease.

It is generally believed that the offspring of feeble mothers show a special tendency to become rickety. The health of the father has not been shown to exert any influence. Parrot maintained that syphilis in the parents may cause rickets in the child, but against this there is, as Jenner has pointed out, one unanswerable argument: in a family of rickety children, as a rule, the younger members are most affected, while in inherited syphilis it is exactly the reverse. Tubercle and scrofula have no definite connexion with rickets; in fact they are seldom met with in the same subject. A deficiency of lime in the water of the district has also been stated to be a cause of this disease, but this is evidently not the case, for rickets is far more common in London, which is supplied with water containing a considerable amount of lime, than in Glasgow, where the water contains merely a trace.

**Symptoms.**—These may be divided into general symptoms and those referable to the changes in the bones. The *general symptoms* are the following: the child may be thin, but is more often apparently well nourished, sometimes very fat. Its mucous membranes are pale, but the cheeks are often redder than natural. On careful examination with a lens, however, this will be seen to be caused by a network of dilated capillaries in the true skin. A most characteristic sign is profuse sweating of the forehead when the child is asleep, the rest of the body often being at the same time hot and dry, though the thermometer rarely shows any marked elevation of temperature. There is often general tenderness of the body, so that any handling is painful; partly in consequence of this and partly from the heat of the body, the child kicks off its bed-clothes at night, so that it is sometimes impossible to keep it covered, unless it is made to sleep in flannel drawers and a jersey. The digestion is often good, but there is a tendency to attacks of gastric catarrh, with a furred white tongue and perhaps vomiting. The motions are clay-coloured and offensive. Flatulence is common, and owing to the weakness of the muscles, which is often a marked effect of rickets, the child usually becomes pot-bellied. The spleen is frequently enlarged, and in some cases the liver also. The urine, as a rule, presents nothing characteristic. It may contain

an excess of phosphate of lime, but this is not the result of softening of the bones, but evidence of imperfect assimilation.

The *changes observed in the bones* appear early in the disease. They consist of enlargement of the articular ends, most marked at the points of junction of the shaft with the epiphyses; in consequence of which the joints appear to be swollen. The enlargement is also especially marked at the junction of the ribs with their cartilages, which form prominent rounded swellings, felt and sometimes clearly seen through the skin, giving rise to the appearance which has been termed the "rickety rosary." At a later period, owing to the softness of their structure, the bones bend, giving rise to various characteristic deformities. Humphry and Langenbeck have called attention to the want of growth in length often observed in rickets. Humphry says that the humerus and femur are about one-fourth shorter in rickety subjects than in healthy individuals of the same age. The most important deformities arising in different parts are the following:—The *head* early appears large, the forehead being especially protuberant, and the face small. The fontanelles, especially the anterior, are very slow in closing; the bones of the skull may be thickened, forming prominent ridges on each side of the sutures, though occasionally in the occipital region they are unduly thin. The *spine* in young children usually presents one long curve backwards from the lower cervical region to the coccyx, with a compensating curve forwards in the neck. In older children there may be merely exaggeration of the normal curves. The *chest* presents very characteristic deformities: the sternum projects somewhat forwards, with a deep depression on each side caused by the sinking-in of the soft newly-formed part of the ribs at their anterior extremities. The deformity is commonly termed "pigeon-breast." The depression is less on the left side, as the ribs are supported by the heart. The lower ribs are pushed outwards by the abdominal viscera. The angles of the ribs are less obtuse than natural. The *clavicles* show merely an increase of the normal curves. The *humerus* is usually bent outwards at the insertion of the deltoid; the *bones of the forearm* are bent outwards in the lower third. The *pelvis* is narrowed from before backwards, more especially if the deformity commences before the child has learned to walk. The *femur* presents a single long curve forwards. The *tibia* and *fibula* are bent forwards and outwards or forwards only in their lower thirds. The deformities here mentioned are the most common, but other varieties may be met with. As the child grows older it frequently becomes knock-kneed or bow-legged.

Dentition is usually much delayed. This is an important symptom, and it is, therefore, necessary to remember the dates at which the teeth should appear. This may be easily done by the following formula, which is accurate enough for clinical purposes. Taking the teeth in anatomical order, commencing with the central incisor, they appear at the following dates in months: 7, 9, 12, 12, 24.

**Progress and Prognosis.**—Under proper treatment rickets can usually be cured. The bones then rapidly become solid and firm, and remain permanently fixed in their abnormal shape. The concavities of the curves become partly filled up to give the bone the necessary strength, while absorption takes place laterally to preserve lightness. This is often very marked in the femur, the antero-posterior diameter of which may be double the transverse. After recovery from rickets there is frequently early union

of the epiphyses, by which the whole body is stunted. Muscular development is, however, often good, and the patient may eventually become sufficiently powerful, the previously soft bones becoming unusually dense.

Rickets infinitely rarely causes death directly, but by impairing the power of coughing it indirectly causes the fatal result in a considerable proportion of cases of bronchitis in children.

**Pathology.**—Beyond the fact that the red corpuscles have been found deficient in number, examination of the blood has thrown but little light on the disease. The nature of the enlargements of the liver and spleen is somewhat doubtful and requires further investigation.

In the bones the essential features of the morbid process are, first, an exaggeration of the processes immediately preparatory to the development of true bone; secondly, an imperfect conversion of this preparatory tissue

into true bone; and thirdly, a great irregularity of the whole process. In rickets there is a growth of soft bone, but no softening of healthy bone. Such osseous tissue as has been developed before the disease commenced remains unchanged, unless absorbed in the process of the formation of the medullary canal. The pathological appearances are best studied in a longitudinal section of a long bone. In normal ossification a thin bluish line is seen between the unaltered cartilage and the newly-formed bone; in this the proliferation of the cartilage-corpuscles is taking place preliminary to the formation of bone. In rickets this line is much thicker than natural, and irregular processes project from it into the cartilage of the epiphyses. The process is wanting in the regularity observed in normal ossification. The proliferating cartilage-cells are heaped irregularly together, and patches in which calcification of the matrix is taking place, are met with, scattered here and there.

Fig. 524.—Longitudinal section of a rickety femur. A thin layer of solid bone formed before the disease began, is seen surrounding the medulla. This has fractured about the middle of the shaft as the soft new bone has bent.

The vascular medullary spaces also which normally penetrate in an even line into the proliferating layer of cartilage show the same want of regularity in their development. Some will be found projecting an eighth of an inch

or more in advance of the others into the unaltered cartilage. These spaces are lined, as in normal bone, with osteoblasts, and bone is formed from them, but the osseous tissue thus produced is softer than natural, and cartilage-cells unaltered, or merely calcified, may be found embedded in it. Beneath the periosteum, especially at the line of junction of the epiphyses with the shaft, a thick layer of reddish, vascular, spongy bone is found. Microscopic examination shows that the osteoblastic layer beneath the periosteum is greatly increased in thickness; the osteoblasts are numerous, but the osteogenic fibres between them are imperfectly developed, and lime salts

are but scantily deposited; the resulting structure is therefore softer than natural.

**Treatment.**—In the treatment of rickets our first endeavour must be to remove those conditions which are known to cause the disease. The child must be as much as possible in the open air and should, if possible, be sent into the country. It must be put to sleep in a bed by itself to ensure fresh air during the night. If it kicks its clothes off it must be made to sleep in loose flannel drawers and a jacket, to avoid the risk of catching cold. A bath should be given, of tepid salt water in winter and cold in summer, every morning and evening, or at least once daily. The diet should be carefully regulated. Before seven months it should consist of nothing but milk; the mother's milk is the best if she be in a state of health to suckle her child; if not, the best cow's milk must be given, diluted at first with twice its bulk of water or barley-water and sweetened with a little sugar. Lime-water may be added if the child vomits or passes undigested milk with its stools. After the child has passed the seventh month a small quantity of properly prepared starch food may be added to the diet, but the supply of milk must not be diminished; at least two pints should be given daily. Underdone meat pounded into a pulp in a mortar, or the juice of raw meat may also be given.

The remedies that are of the greatest service in rickets are iron and cod-liver oil, the former being the more important. They may be given together—one drachm of steel wine and the same quantity of the oil being taken three times a day *immediately after food*. This treatment must be continued for many months. An occasional dose of rhubarb and soda, or compound liquorice powder, may be necessary, and if the tongue be very furred a small quantity of grey powder may sometimes be added. Kassowitz recommends the administration of  $\frac{1}{10}$  of a grain of phosphorus daily either in cod-liver oil or oil of almonds. He states that under its influence all the symptoms undergo rapid amelioration. It is of much importance in preventing deformity in these cases not to allow the child to walk or stand much, but to let it take exercise in donkey-panniers or hand-chairs, and to support those limbs that have a special tendency to bend, with properly constructed steel supports, which will be found of much use, provided they are not too heavy, and do not interfere with the action of the muscles. Methodical friction should also be employed to stimulate the muscles.

**Combination of Rickets and Scurvy.**—Attention has been drawn by T. Smith, Chendale, and T. Barlow, in this country, and Möller and others

Fig. 525.—Femur from a case of scurvy-rickets. *m.* Muscle infiltrated with blood. *pp.* Periosteum raised from the bone by clots of blood. *p.* Clots of blood on bone. *e.* Lower epiphysis separated from shaft.

in Germany, to a disease occurring in young children which is characterized by the following symptoms : after a few days' illness, somewhat sudden swelling takes place, evidently in connexion with the bones, usually in the lower extremities, but sometimes also in the upper limbs. Of all bones the femora are most frequently affected, but most commonly the swelling is not limited to one bone. There is subcutaneous œdema, varying in amount. Acute tenderness forms a most prominent symptom, and the slightest movement evidently causes severe pain. The limbs consequently lie motionless, a condition which has been termed "pseudo-paralysis." The swelling of the bones is usually most marked near the ends of the shafts, and in extreme cases the epiphyses are found to be separated. Other bones often become affected subsequently to the first appearance of the disease. There is usually some elevation of temperature, but it seldom exceeds 101.5° F. Spongy gums are met with in about half the cases ; purpura, hæmaturia, and subconjunctival hæmorrhage have also been noted. The child soon becomes extremely anæmic, and, if not properly treated, rapidly emaciates and dies.

The fatal cases, when examined after death, have shown that the pain and swelling are due to a copious extravasation of blood beneath the periosteum stripping it widely from the bone. The disease has been described by German writers as "acute rickets," but Barlow, who has carefully analysed 22 cases, states that in three the signs of rickets were very pronounced, in seven moderately well marked, in nine slight, and in three absolutely wanting. He therefore concludes that the scurvy is the essential part of the disease, the rickets being more or less accidental, and at most favouring the occurrence of the subperiosteal hæmorrhages. In every case the disease seems to have been the result of improper feeding, chiefly an insufficient supply of milk in infants, and want of vegetables in older children. Barlow therefore suggests the name of "infantile scurvy" for the disease. The treatment is usually successful if the disease be recognized in time. Milk, lime-juice, and fresh vegetables, with plenty of fresh air, soon relieve the symptoms.

#### MOLLITIES OSSIUM. OSTEOMALACIA.

**Mollities Ossium** is a somewhat rare disease characterized by softening of the bones. It has been studied with much attention by Curling, Solly, Stanley, MacIntyre, and Litzmann ; and it is principally from their labours that we are acquainted with the chief facts relating to it.

In this disease the bones are bent, or their shafts broken in various parts of the body. Occasionally, though very rarely, only one is fractured ; but in other cases, as in Tyrrell's, there may be as many as twenty-two fractures, or, as in Arnott's, thirty-one. These fractures are unattended with any attempt at the formation of callus. The body becomes singularly and distressingly distorted. On examining the bones after death the periosteum is seen to be usually redder and more vascular than natural. A section of the bone can readily be made with a knife, the osseous tissue feeling soft and gritty as it is cut. The medullary canal of a long bone is increased in diameter, the spaces of the cancellous tissue are enlarged by coalescence, after destruction of the bony trabeculae, and the compact tissue is more spongy than natural, from widening of the Haversian canals. However advanced these changes may be, there is always a thin unaltered layer of compact bone immediately beneath the periosteum. The

enlarged cancellous spaces and Haversian canals are filled with an oily, red, grumous, semi-fluid substance. Microscopic examination shows, according to Cornil and Ranvier, that the fat-cells of the medulla have disappeared to a great extent, their place being occupied by small round cells, spindle-cells, and some flattened cells. Hæmorrhages into the medullary substance are common, and small cysts are often met with. In a case described by Poncet the cystic changes were so extensive as to cause considerable swellings of the bones. In the later stages the contents of the medullary spaces include a substance resembling the splenic pulp in appearance, and in which crystals of hæmatoidin may be found. The trabeculæ of bone appear as if they had been acted on by acid. The lime-salts have disappeared from the layers of bone nearest the vessels, leaving the tissue transparent, but still showing the bone-corpuscles just as in bone artificially decalcified. This process gradually advances, and is followed by absorption of the decalcified matrix, while the corpuscles either perish or mingle with the cells of the altered medullary substance.

The term "senile mollities" is sometimes incorrectly applied to the atrophy of old age. In this, however, the enlarged spaces are filled with yellow fat, and not with the characteristic tissue just described.

In chemical composition, the diseased bone has been found by Leeson to be composed of 18·75 parts of animal matter, 29·17 of phosphate and carbonate of lime, and 52·08 of water in every hundred parts.

The **Causes** of the disease are obscure. It has been stated that it is sometimes connected with a rheumatic tendency; as, in every case recorded, the affection has been preceded or accompanied by severe pains, resembling rheumatism. In some instances the patients have been affected with syphilis. It most commonly, though not invariably, occurs in females, as pointed out by Kilian; and in a majority of cases it appears to have a connexion with the child-bearing state. Among 131 patients whose histories have been collected by Litzmann of Kiel, there were 85 females, in whom the disease either appeared during pregnancy or was modified in its course by this condition. Of the remaining 46 patients, 35 were females, and 11 males. It most generally attacks adults, having been observed in few cases under the age of 20; and it may occur even at a very advanced age. Among other conditions which have been supposed to take part in the causation of the disease are prolonged lactation, constant exposure to cold and damp, and insufficient animal food.

Of the various theories which have been advanced to account for the decalcification of the bones may be mentioned, the presence of excess of phosphoric or lactic acid, venous congestion of the medullary substance with resulting excess of carbonic acid, and excessive excretion of lime salts in the urine. There is little evidence, however, to support any of these hypotheses.

The **Seat of the Disease**, according to Litzmann, varies according as it occurs within the child-bearing period or independently of this. In 85 child-bearing women, the whole skeleton was affected in 6 cases only, and all except the bones of the head in two; while in 46 other cases, all parts of the skeleton were diseased in 21, and all the bones except those of the head in six. The percentage of the occurrence of the disease in various parts is shown in the following table:—

	85 child-bearing women.	40 other cases.
Pelvis	96	87
Spinal Column	54	87
Chest	31	80
Lower Limb	17	78
Upper Limb	12	62
Head	8	52

In child-bearing women the disease appears to have a remarkable predilection for the pelvis ; it is probable, however, that a careful examination of all the bones has not been made in all cases.

**State of the Urine.**—The urine is usually abundant and pale in colour ; it tends to deposit a sediment which has been compared to curdled milk. In many recorded cases, it has been found to contain large quantities of phosphate of lime, probably derived from the softening bones, and in one recorded by Solly, a phosphatic calculus was lodged in the pelvis of the kidney. Bence-Jones described in one case the presence in the urine of an albumenoid body, to which he gave the name of “deutoxide of albumen ;” it has the characters of an albumose. It is soluble in hot water. It is dissolved by dilute nitric acid when heated, but precipitates again on cooling. Virchow has described a similar substance in the affected bones.

**Symptoms.**—These are, in the early stages, extremely obscure and insidious. The patient complains, in the first instance, of wandering pains about the limbs and trunk which assume usually a rheumatic character, though they have been observed to be of a much more severe, persistent, and intractable nature than those that occur in any form of rheumatism. The patient becomes debilitated, unfitted for exertion, and emaciated. Spontaneous fracture now occurs in some bones under the influence of the most trivial causes ; others become bent, and the body consequently greatly misshapen and distorted. The deformity of the pelvis is a frequent cause of difficult labour, often necessitating Caesarean section, or Porro’s operation. The acetabula are approximated by the weight of the body pressing on the heads of the femora ; thus the oblique diameters are diminished, while the pubes is carried forward, the horizontal rami often coming nearly in contact. If the patient is not pregnant, menstruation remains regular in most cases. Death usually results from general exhaustion, after a period varying from two to six years.

**Diagnosis.**—The diagnosis of this affection has to be made in the early stages from *rheumatism*. This is not always easy, and, indeed, is at first impossible ; but after a time, when the peculiar phosphatic condition of the urine and the fragility or distortions of the osseous system manifest themselves, the true nature of the affection becomes apparent. With *rickets* it cannot possibly be confounded, as rickets is a disease of childhood, and osteomalacia is peculiar to adult or advanced life.

**Treatment.**—With regard to treatment, but little can be done : the administration of tonics, and a general supporting plan of treatment, may arrest for a time the progress of this terrible affection ; but when once it is declared, it usually progresses from bad to worse, and at last destroys the patient. Opiates may be employed to allay the pain, and in MacIntyre’s case some temporary advantage appeared to result from the administration of alum ; but no remedy has appeared to be of any real advantage in this complaint. Cases

have however been recorded in which, after very extensive softening of the bones, complete recovery has taken place.

The close relation of the disease to pregnancy, and its rapid increase with recurring gestations, has suggested the production of an artificial menopause as a possible means of relief or cure. For this purpose removal of the ovaries has been practised by Fehling of Basel and Trizzi of Milan, apparently with considerable success.

#### OSTEITIS DEFORMANS.

In 1876, Paget read a paper before the Royal Medical and Chirurgical Society of London on five cases of a general disease of the bones to which he gave the name of *osteitis deformans*. Since that time a considerable number of cases have been recorded in this country and in France, which have more or less closely agreed with Paget's original description.

The **Causes** of the disease are obscure. It most commonly commences about the age of fifty, and appears to affect the two sexes about equally; for, although of 23 cases observed by Paget only 6 were females, of 43 cases collected by Thibierge 21 were males and 22 females.

The disease appears to have no connexion with syphilis, but in some cases there has been a history of gout or rheumatism. Except perhaps in one instance there has been no evidence of hereditary influence. In some few cases an injury to a bone has preceded the development of the disease.

**Symptoms.**—The most marked feature of osteitis deformans is a gradual enlargement and deformity of certain parts of the skeleton. The disease runs an extremely long course, lasting even as long as twenty years without affecting the general health to any appreciable degree. "The disease affects most frequently the long bones of the lower extremities and the skull, and is usually symmetrical. The bones enlarge and soften, and those bearing weight yield and become unnaturally curved. The spine may sink and seem to shorten with increased dorsal and lumbar curves; the pelvis may become wide; the necks of the femora may become nearly horizontal, but the limbs, however misshapen, remain strong, and fit to support the trunk." The bones chiefly affected are the tibiae, femora and clavicles, and those of the vault of the skull and the spine, but the enlargement is first noticed in one or both tibiae. The bones of the upper limbs, with the exception of the clavicles, are rarely affected in so marked a degree as those of the lower limbs. More or less pain is a common symptom; it is generally most marked in the early stages, and being situated in the bones it is thought to be rheumatic. The pain is not usually worse at night.

In four of Paget's cases the patient gradually became blind; in one from choroiditis and in three from retinal hæmorrhages. Hutchinson has also recorded a case in which choroiditis was present.

**Pathology.**—The bones examined after death show changes evidently of an inflammatory character. The skull is uniformly thickened, but in the long bones the compact tissue is chiefly affected. The thin layer of compact bone on the articular surface is thickened and encroaches on the cancellous tissue. The thickened bone is soft and spongy, its substance is very vascular, and its surface is grooved with lines for the vessels of the periosteum. Neither the periosteum nor the medulla presents any marked change.

Microscopic examination of one of Paget's cases by Butlin confirmed the opinion that the disease is inflammatory. He says: "The whole microscopic

architecture of the bone had been altered; the structure appeared to have been almost entirely removed and laid down afresh on a different plan and in a larger mould." The enlarged Haversian canals contained a tissue closely resembling that found in ordinary rarefying osteitis, but more fibrillar and containing fewer cells. In some of the canals the process of destruction was evidently progressing, Howship's lacunæ with osteoclasts (p. 259) being seen, while in other parts new bone was being formed by osteoclasts. Sharkey found similar changes and noted an irregularity in the arrangement of the bone corpuscles and shrinking of the lacunæ.

In three of Paget's first cases sarcomata of bone appeared late in life; and of a total of 19 deaths, collected by Thibierge, 10 occurred from malignant disease, affecting amongst other parts, the dura mater, lung, cerebellum, humerus and radius.

No **Treatment** seems to be of any use.

#### ACROMEGALY.

ACROMEGALY is a rare disease chiefly characterized by symmetrical enlargement of certain parts of the skeleton, notably of the hands, the feet and the face. It was first described as a distinct affection by Pierre Marie in 1885, who founded his description on two typical cases in the Salpêtrière Hospital. Cases presenting similar symptoms had previously been recorded, and since the publication of Marie's monograph a considerable number of cases have been met with in this country and elsewhere. In Souza-Leite's thesis, published in 1890, details of thirty-eight cases are given.

The **Causes** of acromegaly are obscure. The disease affects both sexes, but women appear to be more liable to it than men. It usually commences between the ages of 20 and 26. There is no evidence to show that syphilis stands in any causal relation to the affection, nor does it appear clear that the relation to gout and rheumatism is more than an accidental one.

**Symptoms.**—The most obvious symptoms of acromegaly are the enlargements of the hands and feet, and of the face. The enlargement of the hands takes place without appreciable alteration of form, except that the width and thickness are more increased than the length, so that the term "battledore hands" has been applied to them by Marie. There is no swelling or œdema, the soft parts being merely increased in proportion to the bones, so that the hands come to resemble those of a giant. The arms and forearms are usually not enlarged, and in cases where some hypertrophy of these parts was noted it was not in proportion to that of the hands. The feet are affected similarly to the hands, the enlargement not extending above the ankles. The cranium is rarely much affected, but there may be some increase in its antero-posterior diameter. The alteration in the face is the most striking feature, and the patient may be quite unrecognizable by his friends. It becomes greatly increased in length and oval in form, the enlargement affecting chiefly the supraciliary ridges, the margins of the orbits, the nose, the malar bones and, more than all, the lower jaw. The soft parts of the face generally are thickened; the lower lip is much enlarged and the chin prominent. There is marked curvature of the spine in the cervical and dorsal regions so that the head is thrown forwards. The sternum is prominent and the clavicles and ribs enlarged. In a large number of recorded cases the thyroid gland has been diminished in size; in some it appeared to be normal, and in a few instances

hypertrophied. The speech is often slow, and the voice deep and harsh. Amongst the symptoms of which the patients complain may be mentioned headache and severe aching pains in the limbs with general debility and depression; the appetite may be increased, and excessive thirst has been a troublesome symptom in some cases. According to Marie the onset of the disease in females is often accompanied by amenorrhœa.

**Diagnosis.**—Acromegaly is easily distinguished from myxœdema by the fact that in the latter affection the swelling is limited to the soft parts. The principal differences between acromegaly and osteitis deformans are, according to Marie, that in the former the face, and in the latter the cranium is chiefly enlarged; in acromegaly the general outline of the face is oval, in osteitis deformans triangular; in acromegaly the hands and feet are chiefly affected and the bones are merely enlarged, whereas in osteitis deformans the long bones are chiefly affected and become remarkably deformed; acromegaly usually occurs before 35, osteitis deformans after 40. A remarkable condition has been described by Marie under the name of "hypertrophic pulmonary osteoarthropathy," in which enlargement of the bones and joints occurs as the result of chronic pulmonary disease. In this affection the enlargement of the hands affects chiefly the wrist and fingers, the extremities of the latter being bulbous. Marie has also pointed out the features which distinguish acromegaly from a rare affection of the bones of the face, first described by Virchow under the name of *leontiasis ossea*. It seems hardly likely that the two diseases can be mistaken. *Leontiasis ossea* is characterized by great and irregular enlargement of the face and bones, the two upper jaws being as a rule first affected. Masses of bone project externally and also fill the antra and block the nose. The affection very slowly spreads to the other bones of the face and even to those of the cranium. The new bone is spongy in structure. In the few recorded cases the disease has begun in early life, but nothing definite is known as to its causation.

**Pathological Anatomy.**—The most remarkable condition which has been met with in the post-mortem examination of cases of acromegaly is enlargement of the pituitary body. In seven autopsies collected by Souza-Leite this condition was constantly present, but in more than one of the fatal cases in this country the pituitary body appeared normal. In one case the gland was as large as a hen's egg, and in another it pressed upon the optic commissure and nerves, causing optic neuritis and blindness. The enlargement appears to affect the anterior lobe of the gland, and in a case examined by Marie and Marinesco, these observers found true hypertrophy of the glandular tissue, associated with degenerative changes and fibrous overgrowth. In Godlee's case the enlargement affected only the right half of the anterior lobe; the microscopic appearances differed from those of the normal gland in an irregularity of the gland tubes and the cells lining them. Atrophy of the thyroid, sclerosis of the sympathetic ganglia and persistence of the thymus are among the other conditions which have been met with. The enlargement of the bones is apparently the result of a new formation of spongy osseous tissue and is associated with some rarefaction of the whole bone.

The only **Treatment** which has hitherto been adopted is purely symptomatic. The headache, which may be the most troublesome symptom, has been relieved by antipyrin.

## TUMOURS OF BONE.

**EXOSTOSIS.**—By exostosis is meant the growth of a bony tumour from some of the osseous structures of the body. The causes that immediately give rise to this disease are usually extremely obscure. There can be no doubt that in some instances it is hereditary; but, in general, it occurs without any appreciable exciting cause. It is met with chiefly in the young, developing about the age of puberty. Exostosis appears to originate in two ways: being either primarily formed as true bone developing from periosteum, or being the result of the ossification of a chondroma.

Exostoses are of two kinds—the one hard and compact, the other softer and more spongy. The hard, or **Ivory Exostosis**, is rarely multiple. It is developed from fibrous tissue, but in structure differs both in appearance and composition from normal bone. It is extremely compact and white, having a section closely resembling that of ivory, but possessing a true bony structure, Haversian canals, lacunæ, and lamellæ. In chemical composition, it is found to differ from healthy bone in containing more of the phosphate and less of the carbonate of lime, and also in the proportion of organic matter being smaller. This kind of exostosis grows principally from the flat bones and lower jaw, and, as it is generally of small size, seldom produces much inconvenience, unless it compresses important parts. Thus, Cloquet relates the case of a tumour of this kind growing from the pubic bone, and perforating the bladder; and it is occasionally found to project into the orbit, or from the inner table of the skull, upon the brain. When an ivory exostosis is left to itself, it may become stationary after a time. In some instances it has been known to necrose, and to slough away, as it were, from the parts in which it has been situated. Of this termination Hilton and Boyer have related instances.

The **Spongy or Cancellous Exostoses** grow more rapidly, often attain a considerable size, and are not uncommonly multiple. When multiple, they may be symmetrical in their arrangement, and they are occasionally hereditary through several generations. Exostoses of this form are developed from cartilage. They commence almost invariably at the line of junction of an epiphysis with the shaft, and usually before puberty. When they appear at a later period it has been suggested that they arise from a portion of the cartilage of the epiphysis that has escaped ossification. When growing they are covered with a thin layer of cartilage, but should this become completely ossified, growth ceases and the tumour remains stationary. They are then composed of a thin layer of compact tissue surrounding ordinary cancellous bone; opposite the base of the tumour the normal compact tissue is wanting, so that the cancellous tissue of the tumour is continuous with that of the bone from which it is growing. The exostoses of young subjects thus frequently cease to increase when general growth comes to an end. Those commencing after that time show more continuous growth, and more urgently require surgical interference. Spongy exostoses are usually pedunculated; they are irregularly lobulated on the surface, sometimes resembling the head of a cauliflower. A bursa not unfrequently develops in the superficial tissues covering them.

Their most common seats are the lower end of the femur, the upper end of

the tibia, and the upper end of the humerus. Their structure has been described and figured with Tumours (Vol. I., p. 1025).

The *Symptoms* of exostosis are simply those produced by a hard and slowly growing tumour, connected with a bone and pushing forwards the soft parts covering it. In many cases it produces serious inconvenience by its pressure, either upon neighbouring organs or mucous canals; or it may occasion ulceration of the skin lying above it. In some cases, the presence of an exostosis may be connected with an arrest of development of the bone from which it springs. Thus I have seen the lower third of the ulna completely arrested in its development by the formation of an exostosis at the lower part of the middle third, the bone being permanently shortened and dwarfed below this point.

*Treatment*.—If an exostosis be so situated as to occasion inconvenience or deformity, it will be necessary to remove it; and as it is a local disease, there is no fear of its return, provided this be fully done. If, however, the whole of it be not taken away, it may grow again. The removal of these tumours is best effected with a Hey's saw, or cutting forceps, or a chisel and mallet. In some situations, as when close upon joints, or springing from the cervical vertebrae, they cannot be interfered with; and in other cases, as occasionally happens in the neighbourhood of the orbit, their density and hardness may be such that the saw can scarcely work its way through them.

The **Spongy Exostosis of the Ungual Phalanx of the Great Toe** is of such frequent occurrence as to deserve special attention. It springs from the upper surface of the phalanx, near its anterior extremity, pushing the nail upwards and backwards. It may reach the size of half a cherry and project beyond the nail, giving rise to great pain and inconvenience in walking. The only treatment is complete removal of the growth with the cartilage covering it from which it grows, as if any of this be left behind, the tumour will recur. The removal is thus effected. The toe must be made bloodless by Esmarch's method. The nail is then removed in order to expose the growth thoroughly. A circular incision is then made round the tumour to the bone, and the base is cut through with a gouge or chisel. The tumour should then be carefully examined, and if it appears that any of the cartilage covering it has been left behind, this should be cut away with a gouge.

**CHONDROMATA OR CARTILAGINOUS TUMOURS OF BONE** are often met with. These have already been described when speaking of enchondroma and its pathology (Vol. I. p. 1022), and need not, consequently, be more than alluded to here. They usually require resection or amputation of the affected bone, according to the attachment and size of the growth.

**FIBROMA OF BONE**.—Fibromata are not common in bone; when they do occur they spring from the periosteum. The situation in which they are most frequently met with is the base of the skull, from which they project downwards into the pharynx and posterior nares, forming the disease known as fibrous polypus of the nose (see Diseases of the Nose). They are also occasionally met with in connexion with the jaws.

**CYSTIC TUMOURS OF BONE** are extremely rare, if we exclude those met with in the jaws, which arise in connexion with the teeth, and those in which the cysts are merely an accidental formation in a solid tumour. The cystic tumours described by the older writers under the name of *Spina Ventosa* are always sarcomatous growths in which cysts have developed.

Nélaton describes simple cysts of bone containing a clear or reddish serous fluid, and lined with a smooth membrane having the appearance of a serous membrane, as being occasionally met with in the long bones. He states that the cysts may be unilocular or multilocular. He describes but one case as having come under his observation. The tumour occupied the femur, from the trochanter to one inch from the condyles, expanding the whole shaft to a great size. It was composed of an agglomeration of cysts, mostly about the size of a walnut, and separated from each other by bony septa. The cysts were filled with reddish serum. He states that two similar tumours have been recorded, one by Breschet and one by Travers.

The chief symptom is a slow and almost painless enlargement of the affected bone, forming a smooth, round or oval growth. The skin covering it is of normal colour. When a certain size has been attained, so that the shell of bone is expanded into a very thin lamella, and before it is perforated, pressure on the tumour occasions a peculiar crackling or rustling noise, like that produced by pressing together a broken egg-shell, or the crackling of tin-foil. Under this, the elasticity or even semi-fluctuation of the tumour may be felt. The fluctuation is particularly marked after a time, when the osseous envelope has become still more expanded, or is partially or wholly absorbed. When the shell of bone becomes very thin, spontaneous fracture may take place.

Fig. 526.—Cells from Spindle-celled Sarcoma.  
Tumour of Scapula: First recurrence.

Cysts of the jaws will be more fully described with the diseases of those parts.

**Treatment.**—When the tumour is very large, removal of the affected bone may be necessary, but if it be of moderate size, so as not to have materially affected the integrity of the bone, it may suffice to remove one side of the wall of the cyst

by the trephine or by excision, and then the cavity may be allowed to granulate, and its walls to contract. This plan has proved especially successful in some of the cystic tumours of the lower jaw; and I have practised it with success in a small cyst forming in the outer condyle of the humerus.

**HYDATIDS.**—Hydatid disease of bone is rare. Forty-nine cases were collected by Gangolphe in 1886, and Targett has recently increased the number to seventy-six. Of 14 specimens in the London Museums, Targett finds that in 8 the femur or tibia is affected, in 2 the pelvis, and in 4 the spine. The disease begins in the cancellous tissue, and causes gradual expansion and finally perforation of the bone. In the early stages the cancellous tissue is found infiltrated with small cysts; the growth of the parasite taking place by budding from the outer surface of the parent cyst, and not within it as is usually the case. Suppuration, necrosis, and spontaneous fracture are occasional results of the disease; and when the articular end of a long bone is affected, the neighbouring joint may be invaded. The disease is likely to be mistaken for a central sarcoma or for osteitis and necrosis from other causes. The *Treatment* must depend on the situation and extent of the disease, and in the

case of the long bones the Surgeon must consider the possibility of removing the diseased part of the bone by gouging or excision before resorting to amputation.

**SARCOMATA OF BONE—PRIMARY MALIGNANT TUMOURS OF BONE.**—Carcinoma never occurs primarily in bone; the tumours formerly classed as primary encephaloid or scirrhus cancer of bone, osteo-cancer, osteo-cephaloma, &c., all belong to the class of sarcomata. Carcinoma only attacks bone as a secondary growth, or by extension from a primary growth commencing in the epithelium of a gland, of the skin, or of a mucous membrane.

Our knowledge of sarcoma of bone has been greatly increased by the investigations of Gross of Philadelphia and Butlin of London. For the purpose of classification, sarcomata of bone are divided, first into *central*, springing from the cancellous tissue or the medullary canal, and *periosteal, subperiosteal* or *peripheral*, arising on the surface of the compact bone; secondly, they are subdivided according to the structure of the growth, into *spindle-celled, round-celled, mixed spindle- and round-celled, and myeloid*. Gross makes a separate division for osteoid or ossifying sarcoma, and separates cartilaginous tumours entirely, placing them in another group. Butlin classes ossifying sarcomata and chondro-sarcomata, according to the form of the cells (spindle, round, or

Fig. 527.—Ossifying Spindle-celled Sarcoma Tumour springing from the Scapula.

Fig. 528.—Microscopic Characters of the Tumour in its second Recurrence. Multinucleated Myeloid Cells.

mixed,) met with in the growing margin of the tumour. The microscopic structure of these various forms of sarcoma has already been described in the Chapter on Tumours (Vol. I. p. 1037). Gross gives the following as the relative frequency of the different forms of sarcoma among the 165 cases affecting the long bones which formed the basis of his paper: central myeloid sarcoma, 70; periosteal ossifying sarcoma, 45; central spindle-celled sarcoma, 16; periosteal round-celled sarcoma, 13; central round-celled sarcoma, 12; periosteal spindle-celled sarcoma, 9. Of all forms of sarcoma, out of 149 cases, 87 occurred in males and 62 in females; and of 147 in which the age was ascertained, 110 occurred before 30. The central spindle-celled sarcoma was the only form that Gross found to occur more frequently after 30 than before. In about half the cases the disease was attributed to injury. The various long bones were affected in the following order: femur, 67; tibia, 46; humerus, 25; fibula, 13; ulna, 7; radius, 6; ulna and radius, 1. The following table, showing the malignancy of the various forms of sarcoma affecting the long bones, is so important that I reproduce it entire.

FORM OF SARCOMA.	INFECTED NEIGH- BOURING SOFT PARTS.	INFECTED LYMPHATIC GLANDS.	RECURRED LOCALLY AFTER REMOVAL.	INFECTED THE SYSTEM GENE- RALLY.
	Per cent.	Per cent.	Per cent.	Per cent.
PERIOSTEAL :—

Round-celled	54	7.69	50	66.66
Ossifying	40	6.25	41	65.62
CENTRAL :—				
Round-celled	66	8.33	25	33.33
Spindle-celled	18	0	20	23.07
Myeloid	12	0	8	22.72

When internal organs become affected, the secondary growths will generally be found in the lung, and sometimes also in the liver and other viscera. The secondary tumours, as a rule, reproduce the special features of the primary, such as ossification, calcification, development of cartilage, &c. (Fig. 528).

In **Central Sarcoma of Bone** the tumour springs from the cancellous tissue

or the medullary canal. It is usually situated at or about one articular end, expanding the bone, until in many cases a thin shell only is left surrounding the mass. The symptoms may at first closely resemble those of chronic periostitis and osteitis, or abscess of bone, the only means of diagnosis sometimes being the application of a trephine. In most cases, however, the pain is not so severe as in chronic inflammatory affections. However extensively the articular end of the bone may be destroyed by the tumour, the cartilage of the neighbouring joint never becomes implicated. The close proximity of the tumour to the joint may lead to the disease being mistaken for tuberculous disease of the articulation, as I have more than once seen

Fig. 529.—Myeloid Sarcoma of Head of Tibia. The tumour is extensively cystic.

happen in myeloid sarcoma of the lower end of the femur. The cartilage, however, being undestroyed, there is in these cases usually a considerably greater degree of movement than is possible in tuberculous disease. Central sarcoma, so long as the disease is confined within the walls of bone, develops but slowly and shows but little tendency to infect the system, but when once it extends beyond and implicates the soft parts, the danger becomes greatly increased. Spontaneous fracture is not uncommon. Central sarcomata are of four kinds, myeloid or giant-celled, spindle-celled, round-celled, and mixed spindle- and round-celled. These are further modified by the formation of cysts, calcification, ossification, and the development of cartilage. Eighty-one cases collected by Batlin showed the following structure : round-celled 22, of which 17 were

simple, 1 calcified, 3 ossifying, and 1 fibroid; spindle-celled 19, of which 15 were simple, 2 developing cartilage, and 2 calcified; mixed-celled 22, of which 18 were simple, 3 ossifying, and 1 calcified; and myeloid 17, of which 14 were simple, and 3 contained bony spicula. According to Gross, if the long bones

Fig. 530.—Giant-cell from Myeloid Sarcoma.

Fig. 531.—Fusiform and oat-shaped Cells from Myeloid Tumour.

only be considered, myeloid tumours form a much larger proportion than in Butlin's table.

All the central sarcomata, except the myeloid, tend to diffuse themselves widely through the medullary canal; the myeloid tumour often remains tolerably sharply limited to the articular end of the bone in which it commenced, and may even be shut off from the medullary canal by a dense plate of new bone. As a central sarcoma grows, the bone becomes "expanded" by it till a mere shell, often deficient in parts, is left. If the tumour be very soft or contain cysts, this may in parts give the sensation of "egg-shell crackling."

In **Peripheral, or Periosteal Sarcoma**, there is no expansion of bone. The tumour is from the first elastic and fixed, commencing usually at one side, but often at a later period embracing the whole bone. The forms of sarcoma met with in 80 examples collected by Butlin were the following: round-celled 30, of which 22 were simple, 6 ossifying, and 2 chondrifying; spindle-celled 22, of which 13 were simple, 3 ossifying, and 6 chondrifying, and in some cases subsequently becoming ossified or calcified; mixed round- and spindle-celled 28, of which 11 were simple, 6 ossifying, 5 calcifying, and 6 developing cartilage. When the tumour ossifies or calcifies it does not penetrate deeply into the compact tissue; when these changes do not take place the bone becomes eroded and spontaneous fracture is very likely to occur. The pain accompanying a subperiosteal tumour is usually less severe than that of a central sarcoma. The tumour varies in consistence according to its nature from firm and elastic to semi-fluctuating. In some cases pulsation of a

thrilling kind, with or without a bruit, is distinctly perceptible especially in an advanced stage of the disease, when the vascularity of the tumour is greatly increased. Cysts are not uncommon in the softer forms of sarcoma.

**Diagnosis.**—Central sarcoma of bone in its early stages so closely resembles *chronic osteitis and periostitis* that it is frequently impossible to come to a correct conclusion as to the nature of the case without cutting down on the bone and applying a trephine or gouge. In the later stages the diagnosis becomes more easy; the great enlargement of the bone, the occurrence of "egg-shell crackling" on pressure, and more especially pulsation when it is present, making the nature of the case clear.

From *cystic tumours* of bone the diagnosis is often impossible, as the great

Fig. 533.—Expansion of Lower End of Femur by a Myeloid Sarcoma.

Fig. 534.—Myeloid Tumour of Lower Jaw (79 diam.), showing the manner in which the bone is invaded. a. The deep surface of the Scapula.

majority of "cysts of bone" (except in the jaws) are really soft sarcomata with cysts developed in the tumour. It is only by cutting into the affected part that the nature of the disease can be ascertained. From *disease of the neighbouring joint*, the diagnosis is made by observing that the joint does not form the centre of the swelling, and that movement, although limited, is not painful, and is unaccompanied by grating or crackling in the articulation. Should the tumour have penetrated the joint, which is very rare, the difficulty of diagnosis becomes greatly increased.

Peripheral Sarcoma is most frequently mistaken for a deep-seated *chronic abscess*, but the absence of true fluctuation, the presence of a rounded edge to the tumour, and its fixed attachment to the bone will usually enable the Surgeon to recognise its true nature. Sometimes the nature of the disease is revealed by the occurrence of spontaneous fracture, as in the case represented in Fig. 535. In all doubtful cases the swelling must be punctured with an

aspirator. Even when the presence of a tumour is evident, it is not always easy to make sure that it is attached to the bone. Examination under chloroform, with complete relaxation of the muscles, will usually, however, overcome this difficulty.

A consolidated *aneurism* has been mistaken for a sarcoma of bone, and amputation has been performed on this supposition, as in the case represented in Fig. 450. The opposite error has, however, more often been made, a soft pulsating sarcoma being taken for an aneurism. The distinction between these diseases has already been given at p. 112.

Having ascertained the presence of a tumour, it remains to determine the

Fig. 535. — Peripheral Spindle-celled Sarcoma of Shaft of Femur sawn open. Spontaneous Fracture.

Fig. 536. — Peripheral Spindle-celled Sarcoma of Shaft of Femur, successfully Amputated at Hip-Joint.

*nature of the growth.* In many cases this cannot be done. If the tumour is of slow growth, very firm, of considerable size, lobulated on the surface, very clearly defined, and immovably fixed to the bone, it may be a simple chondroma. If, with the same symptoms, however, it is of more rapid growth, it may be a sarcoma developing into cartilage. The distinction is very important if it can be made, for a simple chondroma is an innocent tumour, and the Surgeon in removing it may carry his knife close to the growth, but a chondrifying sarcoma is usually very malignant, and amputation must be done high above it. Unfortunately the distinction is often impossible. When the tumour is central and situated at an articular end of a long bone, especially the upper end of the tibia, the lower end of the femur, the upper end of the humerus or the lower end of the ulna, or in the lower jaw, the chances are greatly in favour of its being a myeloid sarcoma. According to Gross, nearly

70 per cent. of the central tumours of the long bones are of this nature. Myeloid tumours are often somewhat globular in form, and cysts are very common in them. They usually occur between 25 and 35, and grow slowly without affecting the constitution. When the central tumour affects the shaft of a bone it is probably one of the more malignant sarcomata, either round-celled, spindle-celled or mixed, myeloid being very rare in this situation.

The peripheral sarcomata cannot be clearly distinguished from each other. Myeloid so rarely commences superficially, that it may practically be excluded. If the lymphatic glands are affected, it is most probably a round-celled

Fig. 537.—Rapidly growing malignant Tumour of the Head of the Humerus, with Spontaneous Fracture of the Shaft.

Fig. 538.—Section of rapidly growing malignant Tumour of Head of Humerus: upper end and Head of Humerus destroyed, but Articular Cartilage unaffected. Tumour divided by white vertical line—the Periosteum: inside which only were the second Spicula found.

sarcoma, the spindle-celled form very rarely spreading in this way. All forms of peripheral sarcoma may equally implicate the surrounding soft parts.

In distinguishing between the benign and the malignant tumours, Paget directs attention to the following points: 1. The age of the patient. If below puberty or past middle life the tumour is probably malignant, unless it be a common exostosis. 2. The age of the tumour. If of more than two years' duration, it is probably not malignant. 3. If a tumour of bone have doubled in size in six months, not being inflamed, it is probably malignant.

**Treatment.**—The only possible treatment is by operative interference. If the tumour be simple, it may be possible to remove it by gouging or cutting it out, but if it be one of the malignant sarcomata, the only safe course is to remove the whole bone from which it springs. If from the localized nature of the growth, its origin at an articular end of a bone, and its central position,

there is reason to believe that it is a myeloid sarcoma, it may be sufficient to remove only the part of the bone from which it grows. In the leg this necessitates amputation, but in the lower end of the radius, or the upper end of the humerus, it is sometimes possible to excise the affected part of the bone without removing the limb. In tumours of the lower jaw it is seldom necessary to remove more than half the bone. If part of the bone only be removed, the sawn surface and medullary canal must be carefully examined, and if they do not appear healthy more must be cut away.

If the tumour be peripheral, or if it be a central sarcoma of any kind other than myeloid, no means avail except the complete removal of the diseased bone. These operations are, however, not very promising, as there are few forms of malignant tumour in which secondary growths more rapidly develop. The rapidity of recurrence will, however, greatly depend upon the form of the disease, on the time when *amputation* is performed, and on the part where it is practised. Amputation should always, if possible, be performed in the earliest age of the disease, before general infection has taken place. If the glands be enlarged, little can be expected in the way of ultimate cure.

The selection of the line at which amputation should be performed is of great importance. If the limb be removed for a central growth in the continuity of the diseased bone, there is great probability of a rapid return of the disease in the stump—even when the bone appears healthy to the naked eye at the part cut through, the myeloid sarcoma alone being an exception to this rule. In cases of peripheral disease, this return may not take place in the same bone; indeed, I have seen one case of the kind in which the disease affected the lower end of the tibia, and that bone was amputated in its upper third; in this case, after a lapse of some months, fatal recurrence of the disease took place in the pelvic bones, but not in the stump. As, however, the peripheral is more rare than the central form of the disease, and as there are no means of ascertaining the precise kind before removal, the rule, I think, should be absolute to amputate at or above the next joint—at the hip-joint, in malignant disease of the femur; in the thigh, for that of the bones of the leg; and at the shoulder, when the upper arm is affected. When the lower part of the femur, however, is involved, amputation through the trochanters may sometimes be substituted for disarticulation at the hip-joint, the latter operation being so formidable and so fatal that the Surgeon may think it advisable not to subject the patient to so serious a risk; or amputation might be performed through the trochanters, and the head of the bone then resected. In this way the severity of the operation and the extent of wound would be lessened, whilst the whole of the diseased bone would be removed. In cases of myeloid sarcoma it is not usually necessary to remove the whole bone, as the disease almost invariably begins in the articular ends, and rarely extends far into the medullary canal.

In some forms of malignant bone disease, however, the muscles inserted into the affected bone speedily become contaminated, and this contamination may spread widely through the substance or along the sheath of any particular muscle. Hence I think the rule in these cases should be to amputate not only above the diseased bone, but, if practicable, above the origins of the muscles in the neighbourhood of the disease: thus, if there be a malignant tumour of the bones of the forearm, amputation should be done

not only above the elbow-joint but above the humeral attachments of the muscles of the forearm.

The propriety of *excision* of some bones, as of those of the face, in this disease must depend on whether the morbid growth is limited to the structures that can be excised. This operation can rarely be advantageously practised in malignant tumours, there being in general too great an implication of the soft structures in the neighbourhood to justify it.

**SECONDARY SARCOMATA OF BONE.**—All malignant sarcomata, wherever arising, when they become generalized, may form secondary growths in the bones. Thus in a case of sarcoma of the breast under my care some years ago, the fatal result was due to a secondary tumour forming in the sternum. Melanotic sarcoma not unfrequently gives rise to secondary tumours in the medulla or cancellous tissue of bones; secondary alveolar sarcoma is sometimes met with.

**CARCINOMA OF BONE** is always secondary. **Glandular Carcinoma** when it becomes generalized, not unfrequently gives rise to secondary tumours of bone, and is a common cause of spontaneous fracture. Seven cases of this kind have occurred lately in University College Hospital, which are good examples of this. Five occurred after excision of the breast. In three, the secondary tumour formed in the vertebræ; in one, in the ribs; and in one, in the femur. In a sixth case, in an apparently healthy man, the upper jaw was excised for what was supposed to be a primary tumour of the outer part of the upper maxilla and the malar bone. After death a primary scirrhus cancer of the pancreas was found, and the tumour of the jaw presented the same structure. In a seventh case, amputation at the shoulder-joint was performed for a tumour of the upper end of the humerus which was thought to be a primary sarcoma, but which proved to be a carcinoma, secondary to a primary growth in the uterus.

**Squamous Carcinoma** of bone very rarely occurs as a secondary growth; it is usually the result of direct extension from the primary tumour. Two specimens of secondary squamous carcinoma of a rib are preserved in the Museum of University College; in one the primary growth was in the œsophagus, in the other on the penis.

Secondary **Columnar Carcinoma** is still more rare. Bernard Pitts has recorded a case in the Transactions of the Pathological Society of London, in which a growth in the humerus causing spontaneous fracture was secondary to a columnar carcinoma of the rectum.

A very rare form of malignant growth is occasionally met with in the thyroid body, which almost exactly resembles the normal gland in structure. It has a peculiar tendency to give rise to secondary tumours of the same structure in the bones. Cases of this kind have been recorded by Cohnheim, Morris, and others. In some cases they have pulsated strongly.

All secondary cancerous tumours of bone are central, commencing either in the medulla or in the cancellous tissue.

**PULSATING TUMOURS OF BONE—OSTEO-ANEURISM.**—Pulsating tumours of bone, or osteo-aneurisms, are a mixed group of growths possessing in common only one feature, that they pulsate strongly, so as in some cases almost to resemble a true aneurism. The great majority of these are soft **vascular sarcomata**, in which, as Billroth has pointed out, small aneurismal dilatations may exist on the vessels, which form a close network throughout the mass.

Gross states that pulsation was present in 20 per cent. of the myeloid tumours, in 12 per cent. of the central spindle-celled growths, and in 38 per cent. of the central round-celled sarcomata, of which he had collected the records. In peripheral sarcomata pulsation was very rare. It is evident that pulsation cannot be recognized in central tumours until the bony wall has been completely destroyed at one side, and it is possible that the frequency with which central tumours pulsate distinctly after this has taken place may be due to the fact that the vascular mass of the tumour is surrounded on all sides but one by unyielding bone.

Excluding all these cases, two other kinds of pulsating tumours have been described as occurring in bone. In one of these, which is very rare, there is developed in the bone a **vascular erectile growth**, closely resembling a capillary nævus in structure, composed of an infinity of vessels, interlacing in every way, so as to form a soft reddish tumour (Fig. 539). In the second form a hollow cavity is formed in a bone, scooped out of the cancellous structure and filled with blood, partly liquid and partly coagulated, and having arterial branches opening into it. The shell of bone surrounding this cavity is very thin and expanded, and after a time is usually completely absorbed on one side.

This constitutes the "**true aneurism of bone**." Its mode of origin is uncertain. Volkmann suggests that in some cases it may be a soft sarcoma, the original tissue of which has been entirely softened and broken down by hæmorrhage into its substance.

In an important communication on the subject of blood tumours of bone, presented by Roughton to the Royal Medical and Chirurgical Society in 1889, two cases are described which seem to prove their sarcomatous nature. One was a female child, aged four years, under the care of Langton in St. Bartholomew's Hospital for expansion of the upper end of the tibia. Egg-shell crackling was obtained, and an exploratory incision revealed a cavity in the bone containing about two ounces of altered blood and a few clots. The cavity was plugged and gradually closed; three years later the child was perfectly well and no difference could be detected in the measurements of the limb. Microscopic examination of a piece of bone from the wall of the cavity showed that it contained myeloid sarcoma tissue which was remarkably rich in blood-vessels. In the other case, recorded by Max Oberst, a fluctuating tumour as large as two fists occupied the position of the internal condyle of the femur. Amputation was performed, and the thin layer of tissue lining the cyst consisted of myeloid sarcoma in which blood was extravasated from large thin-walled vessels. The patient died subsequently with secondary sarcomatous deposits. Roughton suggests that the blood-vessels form an essential part of the growth—developed possibly from the multinucleated cells—and that these tumours are really angio-sarcomata.

**Situation.**—Pulsating sarcomata may be found anywhere, but are most common in the bones of the skull, the lower end of the tibia and upper end of the femur. Nævoid growths are most common on the skull. The "**true aneurism of bone**" occurs most frequently in the head of the tibia.

**Symptoms.**—When the tumour is merely a highly vascular sarcoma, the symptoms are the same as those already described as indicating a central sarcoma of bone, with the addition of pulsation and bruit. In these the pulsation is very marked and superficial, and commonly of a thrilling character; it may be distinctly expansile; the bruit is usually soft and blow-

ing, but not unfrequently harsh, loud, and whizzing. In the so-called "osteo-aneurism," according to Nélaton, the bruit is often absent. In pulsating sarcomata I have heard the bruit peculiarly loud, rough, and superficial. On compressing the main artery leading to the part of the limb in which the tumour is situated, all movement and bruit commonly cease in it, and the tumour lessens in size. By pressing upon the growth when it is thus diminished, it will commonly be found to have a bony margin, with a central depression. In some cases the tumour is fed by several arterial branches, which may be felt distinctly pulsating under the skin. This is more particularly the case in soft sarcomata occurring upon the bones of the pelvis and the scapula, and then the bruit and pulsation cannot be made to cease in it. All these signs are commonly somewhat intermittent, the pulsation appearing perhaps in the earlier stages of the disease, and disappearing as it advances; or the reverse may occur, the pulsation and bruit becoming distinct as

Fig. 539.—Vascular Erectile Tumour of one of the Parietal Bones.

the disease increases in size and meets with more resistance in its outward growth.

**Diagnosis.**—The distinction between a pulsating sarcoma of bone and the so-called "osteo-aneurism" may be almost impossible; and, indeed, it seems probable that the latter is itself in the majority of cases sarcomatous in nature.

From *ordinary aneurism* the diagnosis of pulsating tumours of bone may be attended with almost insuperable difficulties. So great are these, that there are many cases on record in which the most experienced Surgeons have ligatured arteries for tumours that were supposed to be aneurismal, but which have turned out to be pulsating sarcomata. A principal point to be attended to in making the diagnosis is the situation of the tumour, which may occur in a part of the body where there is no vessel large enough to give rise to such a disease—as, for instance, about the head of the fibula or the outer side of the pelvis. Then, again, its incorporation with the subjacent bone, the want of a distinctly limited and circumscribed outline, and the existence in many cases of plates of bone in the wall of the tumour—giving rise, perhaps, on pressure, to the peculiar rustling or crackling sound characteristic of central bony growths—will enable the Surgeon to come to a correct conclusion. In this

he will be further assisted by its having on compression a soft, doughy, or spongy feel, or appearing as a depression surrounded by an osseous margin. In many cases also, the less impulsive character of the beat of the tumour, the peculiar shrill and tremulous whiz in the pulsation and bruit, will throw light on the nature of the disease. But it cannot be doubted that when tumours of this kind occur in some of the ordinary situations of aneurism, as about the brim of the pelvis, and in the popliteal space, the diagnosis is surrounded with difficulties which no amount of surgical skill may be able to overcome.

From *ordinary tumours of bone*, the existence of pulsation and bruit will always suffice to distinguish the growths under consideration.

**Treatment.**—In the majority of cases the first step in the treatment will consist in rendering the limb bloodless, and making a free exploratory incision into the tumour. If it be found to consist of soft sarcomatous tissue extensively broken down by hæmorrhage, the case must be treated in exactly the same way as a sarcoma which does not pulsate. The favourable result obtained in Langton's case by opening the cavity in the bone and allowing it to granulate from the bottom would justify the adoption of similar measures in any case in which the blood cyst contains little or no soft solid tissue. The result in this instance may seem difficult to reconcile with the fact that the bone around the cavity was found to contain myeloid sarcoma tissue. It must, however, be remembered that the malignancy of a myeloid tumour is very low, and in the case of the jaw, cure has been obtained by freely scraping the growth from the cavity in the expanded bone.

Ligature of the main artery has been practised in several supposed cases of "true aneurism of bone," but in the majority of these the disease turned out to be a soft sarcoma, and consequently no benefit resulted. The growth of the tumour was not even retarded. Roux, however, has recorded a case in which he cured a pulsating swelling in the lower end of the radius by ligature of the brachial artery. Lallemand cured a so-called aneurism of bone by the same procedure. In a patient of Dupuytren's no return of the disease took place for six years, when it recurred, and amputation became necessary.

## CHAPTER XLVIII.

## DISEASES OF JOINTS.—EXCISION OF JOINTS.

JOINTS may become the seat of Inflammatory Affections of an acute or chronic character: of Tuberculous Disease; or of various other morbid conditions, such as more or less permanent rigidity, or Ankylosis, the formation of Foreign Bodies within their cavities, and Neuralgia. In studying these various articular affections, it must be borne in mind that a joint is composed of a number of different structures: of synovial membrane, cartilage, bone, ligament, and capsule, or investing fibrous expansion. Disease may primarily begin in any one of these structures, though eventually the morbid process usually spreads to other tissues entering into the formation of the joint. The merit of having been the first to point out the true mode of studying these affections in reference to the different structures in which they have originated, is certainly due to Benjamin Brodie.

## SYNOVITIS.

**Inflammation of the Synovial Membrane** may occur under two forms: simple or serous, and purulent or suppurative. In the former the inflammation affects the synovial membrane only, and has little tendency to extend to the other structures of the joint; in the latter the capsule, and ligaments, the cartilages and even the bones ultimately become implicated unless the inflammation is arrested by treatment, and consequently this form soon merges into the affection known as acute arthritis, with which it will be described.

Clinically the term Synovitis used by itself is commonly applied only to the serous form.

SEROUS OR SIMPLE SYNOVITIS, is perhaps, the most common of all articular affections. It may be acute, subacute or chronic.

**Acute Synovitis—Causes.**—Simple acute synovitis most commonly arises from blows on the joint, bruises or sprains; but it may occur without apparent external cause, and is then usually due to exposure to cold, especially in rheumatic or gouty constitutions. In these cases it commonly happens that more joints than one are implicated at the same time; the affected articulations are more frequently those that are most exposed by having the thinnest covering of soft parts and by being especially subjected to variations of temperature, such as the knees and ankles. Gonorrhœa is an occasional cause of inflammation of the synovial membrane (see Gonorrhœa, Chap. LXXI.). In very rare cases a subacute form of synovitis with moderate effusion is met with in the secondary stage of syphilis at the same time as the cutaneous eruptions, and effusion into one or more of the large joints, especially the knees, may be a symptom of the inherited disease. Still more rarely acute inflammation with exudation into the joint is met with in acute tuberculosis

as a consequence of miliary tubercle of the synovial membrane. Somewhat sudden distension of the synovial membrane, often with swelling of the whole affected limb, is one of the phenomena not uncommonly observed in Charcot's disease of joints (see Charcot's Disease).

Acute synovitis is an occasional sequela of the acute specific fevers, especially typhoid; the extreme distension of the joint may cause dislocation (see Vol. I., p. 655). Lastly, synovitis is not unfrequently secondary to inflammation and other affections in the neighbourhood of a joint.

**Pathology.**—As uncomplicated acute synovitis is never fatal, we seldom have an opportunity of studying its pathology. It would, however, appear from the examination of joints in cases of synovitis from injury, as well as from the experiments of Richet, Bonnet, and others, who have induced traumatic synovitis in animals, that there is in the first instance an inflammatory congestion of the synovial membrane, with loss of its peculiar satiny polish. The synovia is then increased in quantity, and becomes thin and serous, and after a time intermixed with inflammatory exudation which is poured out with it. If the disease progress favourably, these products are completely absorbed. In more rare cases, the congestion and swelling of the synovial membrane increase, until at last it becomes so turgid and distended with blood and effused fluids, that a kind of chemosis results; a thin purulent-looking fluid is poured out, composed of granular corpuscles—partly migrated leucocytes, and partly desquamated and degenerated endothelial cells—floating in a serous liquid.

In all cases of acute synovitis the fringes of the membrane become swollen, and their vessels injected with blood, so that they form prominent red elevations, especially at the margins of the cartilages. The inflammation in such cases frequently extends to the other structures forming the joint, and the disease then forms one variety of acute arthritis. In other cases, granulations are thrown out on the looser portions of the membrane, and becoming injected with blood-vessels, constitute fringed and villous membranous expansions, lying upon the subjacent cartilage.

**Symptoms of Acute Synovitis.**—The symptoms of synovitis consist of pain and heat and distension of the joint, with fluctuation. If it be large and exposed, the *pain* is sometimes severe, especially at night, being greatly increased by moving or pressing upon the articulation; it is usually sharp, but when the disease occurs in rheumatic or gouty constitutions, it is of a gnawing character. On laying the hand on the joint, it will be felt to be *hot*. The *swelling* of the affected joint is considerable, and evidently depends on accumulation of fluid within the synovial sac, the extreme outline of which is rendered apparent by the tension to which it is subjected. Thus in the knee it rises up high in the thigh under the vasti, to the extent of three or four inches above the upper border of the patella, the swelling being higher on the inner than on the outer side of the limb, whilst in the elbow it rises in the same manner under the tendon of the triceps. There is no effusion into the surrounding tissues; and hence the outline of the joint can be distinctly felt, and *fluctuation* perceived in it. The limb is usually semiflexed, for in this position there is the greatest general relaxation of the ligaments, and it consequently gives the patient most ease. The joint cannot be moved without pain. The constitutional febrile disturbance is tolerably severe, especially if the affection occur in a rheumatic constitution.

The presence of an abnormal quantity of fluid in the joint is always indicated by *fluctuation* and *undulation*, and by the *peculiar shape* acquired by the part. Thus in the knee, which is the most common seat of the affection, the patella will float, as it were, on the fluid. If the distension be not too great, by placing the finger on the knee-cap and pushing it sharply towards the femur it can be felt to sink through the fluid and strike on the bone beneath. This sign is of great importance, as it enables us to distinguish between simple synovitis with effusion, and distension of the joint by soft granulation tissue in the early stages of tuberculous disease. In order to elicit it the patient must be lying down with the muscles of the thigh perfectly relaxed. All the natural hollows about the knee are obliterated; the distended pouches of the synovial membrane project distinctly on each side above the patella, and the hollow on each side of the ligamentum patellæ is obliterated by the infrapatellar fat which is pushed downwards by the pressure of the fluid in the joint. In the elbow there is a soft and fluctuating swelling extending above the olecranon on each side of the tendon of the triceps which forms a depression in the middle line; and in the shoulder there is a general roundness and distension of the articulation.

**Chronic Serous Synovitis** is characterised by effusion of serous fluid into the cavity of the joint without any tendency to the formation of pus, and in fact without any of the ordinary signs of inflammation. The pressure of the fluid distending the capsule and causing swelling and weakness of the joint is the prominent symptom. There is little or no pain, tenderness or heat in the affected joint.

The term **Hydrarthrosis** or **Dropsy of the Joint** has been applied to cases in which the amount of fluid distending the joint is considerable, and the course of the disease extremely chronic. The fluid in these cases partakes in various degrees of the characters of serum and synovia. Hydrarthrosis may arise from at least three distinct pathological causes. First, the effusion may be preceded or accompanied by the ordinary evidence of synovial inflammation, the case apparently being merely one of simple synovitis with very excessive effusion. Secondly, great effusion into the joint is not an uncommon occurrence in Charcot's disease. In this form the effusion is painless or nearly so, and is soon followed by destructive changes in the cartilages and bones with looseness of the ligaments and unnatural mobility of the articulation. (See Charcot's Disease of Joints.) A third form has been described by König under the name of *hydrops tuberculosus* or *tuberculous dropsy* of the joints. (See Tuberculous Disease of Joints.)

In all forms of hydrarthrosis, if the distension is considerable, pouch-like projections of the synovial membrane may push their way through the least supported parts of the capsule, and form cystic swellings in the neighbourhood of the joint. When a bursa communicates with the synovial membrane it becomes distended with the joint in hydrarthrosis, as for example the bursa under the inner head of the gastrocnemius and that beneath the deltoid. It is said that, in some cases, the distension of the joint has been so great that the synovial membrane has been ruptured, and the fluid poured into the surrounding areolar tissue. In these cases, however, it is probable that some destructive change in the synovial membrane preceded its rupture. In more chronic cases the ligaments may become relaxed, and spontaneous dislocation may take place. (Vol. I. p. 655.)

In some cases of chronic synovitis distinct *crackling* will be felt in the interior of the joint, on laying the hand over the articulation, whilst it is freely moved. This appears to me to be due to the existence of bands of fibrinous exudation in the interior of the joint, through which the fluid is pressed by the articular movements, and thus occasions the sensation which is met with under similar circumstances in enlargements of the bursæ, and in fluid effusions in the sheaths of tendons.

**Terminations.**—The termination of serous synovitis will depend mainly on its cause. When simple and uncomplicated, arising as the result, perhaps, of rheumatic influences, it will in most cases end in complete resolution. In other instances, however, as a consequence of inflammatory exudation, warty vegetations or concretions may form within the joint, or bands stretching across its interior or incorporated with its capsule may occasion more or less permanent stiffness. Chronic or subacute synovitis, when simple, usually terminates favourably, although the joint is often left in a weak state from which it may not recover for many months.

The termination of chronic hydrarthrosis will chiefly depend on its cause. If due to Charcot's disease the fluid is usually absorbed more or less completely after some time, but the deformity of the joint remains. (See Charcot's Disease.) In tuberculous dropsy recovery may take place under proper constitutional and local treatment with perfect rest, but not uncommonly the disease gradually develops into ordinary white swelling with destruction of the joint (see Tuberculous Disease).

**Treatment of Serous Synovitis.**—The treatment of serous synovitis depends partly on the severity of the symptoms, and partly on the cause of the disease. If a joint have been injured subcutaneously, and synovitis be apprehended, or indeed have commenced, no treatment will be found more efficacious than the continued application of ice in india-rubber bags of sufficient size to envelop the whole of the articulation; the limb being kept at the same time perfectly at rest on a splint or in a sling. Should well-marked effusion have already occurred, or should the ice fail in arresting it, then, if the patient be young and strong, the application of leeches, followed by fomentations and accompanied by perfect rest of the part on a splint, or on pillows properly arranged, will be the most useful treatment. At the same time, saline purgatives may be given, and the patient kept on a low diet.

If the disease be *rheumatic*, hot fomentations may be applied, and rest of the part maintained in the elevated position; at the same time salicylate of sodium may be given in ten-grain doses, and Dover's powder should be administered if there be much pain at night. If the patient be gouty, colchicum should be given. When the disease is of *syphilitic* origin, the application of blisters, followed by mercury in some form, will be attended with marked success.

In *subacute* or *chronic synovitis* rest is, perhaps, the most important element in the treatment, everything else proving useless unless this be attended to; the limb may be fixed by leather splints, or a starched bandage cut up so that it may be removed to make the necessary applications to the joint. In these cases the uniform pressure obtained by the application of an india-rubber bandage combined with rest will often cause the absorption of the effused fluid. Should this fail, repeated painting with tincture of iodine till the skin is slightly sore, or blistering over the whole of the joint constitutes perhaps the

most useful local measure. In a more advanced stage, counter-irritation by means of stimulating embrocations, together with douches, either of warm sea-water or of some of the sulphurous springs, such as those of Aix or Barèges, will prove most useful; and when all inflammation has been subdued, and weakness of the joint merely is left, the joint should be properly strapped with soap-plaster, spread upon leather, or supported by a well-fitting elastic cap or stocking. Finally, a course of efficient rubbing will often prove most beneficial. Amongst the internal remedies likely to be of most service, may be mentioned the iodide of potassium, either alone or in some bitter infusion.

In *hydrarthrosis* the treatment must necessarily vary with the cause. If it is apparently simple, merely an exaggeration of ordinary chronic serous synovitis, rest combined with the employment of pressure, iodine and blisters must be employed as in chronic synovitis. The internal administration of iodide of potassium, or a mild mercurial course, will sometimes induce the absorption of the fluid. If these means fail, the fluid may be removed by means of the aspirator, after which pressure may be applied by means of the india-rubber bandage to prevent its reaccumulation.

In extreme cases, Jobert, Velpeau, and Bonnet, recommended the injection of the joint with tincture of iodine, diluted with two or three parts of water. In performing this operation a small trochar is introduced into the joint, a moderate quantity of serous fluid is let out, and then a corresponding quantity of the iodine solution is thrown in; and after being left for a few minutes, is allowed to escape. Inflammation of the joint, which is a necessary result of this procedure, comes on. This is treated by ordinary means, and, according to the statements of the French Surgeons, has in no case been followed by any serious consequences, but in several instances a complete cure without ankylosis has resulted. This mode of treatment does not appear to have met with much support in this country; yet it certainly deserves a trial, though recourse should not be had to it lightly, as it is evident that the induced inflammation might exceed the expected limits. In one case of *hydrarthrosis* of the knee, in an old man, in which I employed it, about six ounces of thin synovia were drawn off, and a drachm of strong tincture of iodine was injected. Slight inflammation only ensued; and the disease, which was of two years' standing, was completely cured. The chief points that appear to require attention are that no inflammation be going on at the time, there being no tenderness or pain in moving the joint, the effusion being quite passive, and of a very chronic character; and, above all, that no air be allowed to enter with the injected fluid. This treatment might be of service in the simple form of *hydrarthrosis*, but in the tuberculous form it can hardly be recommended, whilst if the case is one of Charcot's disease it could only do harm. If other methods of treatment fail, the joint may be drained with antiseptic precautions. The tube may be retained for ten days or a fortnight. After dropsy of the joint has been removed, the articulation is usually left weak for some length of time, in consequence of the stretching to which its ligaments have been subjected; here cold douches, massage, and an elastic bandage will constitute the best mode of treatment.

The treatment of tuberculous dropsy will be considered later.

## ACUTE ARTHRITIS.

By *Acute Arthritis* is meant an acute inflammation affecting the synovial membrane and rapidly extending from it to the other structures that enter into the formation of a joint. The disease may arise primarily in the synovial membrane, or the affection of the synovial membrane may be secondary to disease beginning in the bones or in the soft parts around the joint. In the latter case, the symptoms characteristic of acute arthritis do not set in until the mischief has extended to the cavity of the joint. In some forms of acute arthritis the symptoms clearly indicate that the inflammation of the synovial membrane precedes that of the ligaments, while in others the extension is so rapid that all the structures of the joint may seem to be affected simultaneously.

It will be most convenient to describe first the symptoms and pathological changes which are characteristic of acute arthritis from whatever cause it may arise, and afterwards to point out the modifications of the process dependent upon its mode of origin.

**Symptoms.**—The symptoms of acute arthritis that are most marked are the pain, heat, swelling, and peculiar position of the joint. The *pain* is often severe, tensile, and throbbing: sometimes it is so acute, that the patient screams with agony; he cannot bear the bed to be touched, the room to be shaken, or the slightest movement communicated to the limb, any attempt at examination of the joint being attended with unbearable pain. There are usually nocturnal exacerbations, and the pain is commonly referred with especial severity to one particular spot in the joint: thus it is generally felt at the inner or under side of the knee-joint, and at the outer aspect of the hip. The *heat* of the diseased joint is considerable, and is often accompanied by more or less superficial redness. The *swelling* is uniform, involving the whole of the articulation, and not projecting at certain parts of it, as when the synovial membrane alone is affected; it is generally not very considerable, and has a soft and doughy, rather than a fluctuating feel. The *position* of the affected limb is peculiar, and that attitude is involuntarily adopted in which the patient will have the greatest amount of ease: thus, if the knee is affected, it is semiflexed, and the limb is rotated outwards; if the hip, the joint is flexed and the limb abducted and rotated outwards with the knee semiflexed; if the elbow, it is bent. *Spasms* or *startings* of the limb, often of a very sharp and painful character, come on at times, more particularly at night, and are amongst the most distressing symptoms in the more advanced stages of acute disorganization of a joint. Whenever the patient falls asleep, the muscles become relaxed, and the softened ligaments allow the joint to become slightly displaced; a reflex contraction of the muscles immediately takes place and the patient wakes with a painful spasmodic jerk of the limb, inducing a feeling of alarm, that is often very distressing. The *constitutional disturbance* is very rare, and of an active febrile type.

Having reached this stage, in some cases the symptoms gradually subside, the heat lessens, the pain loses its acute character, the swelling slowly diminishes, and recovery takes place after many weeks or months, the joint being left permanently stiffened from contraction of the inflamed ligaments, or sometimes firmly ankylosed, the articular surfaces being united by dense

fibrous tissue or bone, according as the cartilages have been partially or completely destroyed during the acute stage.

More commonly as the disease progresses, *suppuration* takes place within the joint, which becomes hot and red, with a good deal of throbbing pain : the skin covering it is œdematous, and at last fluctuation is perceived where the coverings are thinned. In some cases the suppuration occurs with very great rapidity, and partial or complete luxation of the joint results. In other cases the synovial membrane and capsule of the joint give way without any looseness of ligaments or displacement of bones ; pus becomes infiltrated into the areolar tissue, and burrows widely in the limb. As the joint becomes loosened by the destruction of its ligaments, the bones become mobile, and grate against one another where the cartilage has been removed, thus giving rise to very severe suffering. The cartilages may, however, in some cases be extensively destroyed, and yet no grating take place ; this is owing either to the destruction being limited to the edge of the cartilage, the opposed surfaces being sound, or else to the interior of the articulation being filled up with granulation tissue. But though abscess, either within the joint or external to it, usually forms when the bones grate and the cartilage disintegrates, yet it occasionally happens that these conditions exist—the symptoms indicative of erosion of cartilage, such as painful startings of the limb, grating, and preternatural mobility of the joint, being present—and yet no abscess forms ; all the symptoms subsiding under proper treatment, and the joint recovering, though with a certain degree of ankylosis. But the reverse also may occur. Suppuration may take place in a joint, the synovial membrane and the capsule may give way, and extensive filtration of pus into the deep areolar planes of the limb may occur, without laxity of ligament, preternatural mobility, or grating. This condition may occur in any joint ; I have most frequently met with it in the knee. There the upper and usually the outer part of the capsule generally gives way, and the pus diffuses itself deeply beneath the extensor muscles of the thigh, sometimes even between the periosteum and the bone. In these cases the thigh swells greatly, the limb becomes œdematous, and a deep and obscure sensation of fluctuation may perhaps be felt, more especially towards the outer and lower part of the limb just above the knee. The swelling of the joint has perhaps subsided on the escape of the pus from the cavity, giving a false idea of security, which is confirmed by the absence of signs indicative of disorganization, such as lateral mobility and grating. But on pressing the thigh downwards, the joint will be found to fill, the patella will float again, and there is an evident communication between the synovial cavity and the extensive diffused abscess in the thigh. In cases of this kind the pus will first come to the surface about two or three inches above and to the outer side of the joint ; and on a free incision being made here immense quantities may be let out. In these cases fluctuation is often masked by the œdema of the limb, and by the thickness of the overlying mass of muscle, and will require the closest examination for its detection. After suppuration has taken place, the constitutional disturbance is severe, the patient suffers severe pain, and is worn out by want of rest. After the abscess is opened, unless special means are taken by drainage and antiseptics to prevent the accumulation of decomposing discharges in the articular cavity, septic poisoning or pyæmia is very likely to follow ; or hectic leading to death from exhaustion may occur, unless the diseased part be removed. In other and less

severe cases chronic thickening of the synovial membrane and other parts occurs, perhaps with sinuses leading down to the diseased structures; and in some of the more favourable instances the patient may recover, with a permanently rigid joint.

The *muscles* in the neighbourhood of an inflamed joint often rapidly atrophy and become more or less paralysed. These changes, which have been carefully studied by Le Fort, Charcot and others, are evidently not merely the result of disuse. It is indeed generally believed that the paralysis is induced reflexly as the result of the disease of the joint. That disuse alone is not the sole cause of the paralysis and wasting is suggested by the fact that only certain of the inactive muscles are usually affected. Thus, in disease of the knee, the extensor muscles chiefly suffer; in affections of the shoulder the deltoid alone may waste; whilst in disease of the hip the gluteal muscles are chiefly affected. The electrical reactions of the muscles undergo a marked change so that little or no contraction is produced by either the galvanic or the faradic current. In this there is a marked difference from true atrophic paralysis in which the galvanic excitability is increased. In a case of paralysis of the extensors following an injury of the knee Charcot found that the patellar tendon reflex was not abolished. The paralysis is extremely chronic. It will last for many months after the joint affection, from which it starts, has been cured, and it may lead to permanent atrophy of the paralyzed muscles. The treatment consists in stimulation of the affected muscles, by sea-douches, electricity, and frictions, combined with methodical movements of the limb. Strychnine may be given with advantage when the lower limbs are affected. I have seen this reflex arthritic paralysis chiefly in persons suffering from spinal exhaustion, in neurotic women and in men addicted to sexual excesses.

**Diagnosis.**—*Abscess* may form external to, but in immediate contact with the capsule of a joint, and closely simulate disease of the articulation. In these cases the absence of serious constitutional disturbance, the irregularity of the swelling, greater on one side than on the other, its extension over bony points, as the patella or olecranon, the superficial character of the fluctuation, the absence of all rigidity about the joint or of that preternatural mobility in a horizontal direction which arises from softening of the ligaments, and of other severe local symptoms, such as pain, starting, looseness, or grating, will enable the Surgeon to make a correct diagnosis.

**Pathology.**—It is very rarely that the opportunity arises of examining a joint affected with acute arthritis before it has reached the stage of suppuration. In that stage all the component parts of the joint will be found to present marked changes, varying somewhat with the cause and the degree of acuteness of the inflammatory process. The following may be taken as the appearances in a typical case.

The *synovial membrane* is thickened and intensely injected; if the disease has advanced beyond the earliest stage, the membrane is no longer recognizable as such, being converted into a layer of granulation tissue, the site of the fringes being marked by fleshy vascular projections of the same tissue. The granulations are seldom healthy; most commonly they present the same appearance as those on the surface of an inflamed ulcer of the leg, being covered by a dirty yellowish layer composed of degenerated granulation-cells held together by coagulated inflammatory exudation. If the joint has been

opened, and decomposition of the discharges has taken place, the diseased synovial membrane may be covered by opaque membranous patches almost resembling a diphtheritic membrane. In the later stages of arthritis, the granulations covering the opposed surfaces of any pouches of the synovial membrane will be found to have coalesced, the cavity of the joint being in this way to a great extent obliterated.

Microscopic examination of the diseased membrane shows only the ordinary appearances of inflammation. The endothelial cells covering the membrane have disappeared, and the fibrous layer is first infiltrated with new cells before which the original tissue more or less completely disappears. In the layer of round cells thus formed, new vessels are developed, and granulation tissue is thus produced.

The contents of the synovial cavity are in the very earliest stages composed of thin pus mixed with synovia, but as the membrane very soon ceases to yield its normal secretion, the fluid assumes the characters of ordinary pus. In cases in which the disease stops short of suppuration, an abundant coagulable fibrinous exudation is said to have been observed.

The *ligaments* are early affected by extension of the inflammation to them from the synovial membrane. The bundles of fibres are at first separated from each other by coagulable inflammatory exudation, and the ligaments thus become swollen, and present a waxy or semi-gelatinous appearance. As the disease progresses the fibres become softened, and the ligaments yield, allowing the osseous surfaces to be displaced by the tonic contraction of the muscles, or the weight of the limb. The inflammation extends from the ligaments to the *periosteum of the articular ends of the bones* entering into the joint. The periostitis thus set up usually assumes the osteoplastic form (p. 257), and irregular masses of new bone, often arranged in jagged stalactite-like processes, are formed in the neighbourhood of the articulation. This is more marked in the less acute forms of the disease, or when, after the escape of pus from the joint, the process has become chronic.

The *soft parts in contact with the ligaments* are œdematous in the early stages, but subsequently as the disease advances, they may become fused with the capsule of the joint, so that it is impossible accurately to separate them. Abscesses not unfrequently form outside the joint, having no direct communication with its cavity.

The *articular cartilage* in all cases presents most important changes. These are never primary; in every case it will be found that the morbid process proceeds either from the articular surface, or from the bone beneath. When the latter is the case, the affection of the cartilage is antecedent to the acute arthritis; this condition commencing when the cartilage is perforated, and the joint becomes infected by the products of the disease which has commenced in the bone.

When the cartilage is affected in consequence of acute suppurative inflammation of the joint, the first change observed is a loss of its natural smoothness and polish. Its bluish-white tint becomes more opaque, and often assumes a slightly yellowish tinge. This is followed by loss of substance in those parts at which the opposed articular surfaces are in contact in the fixed position assumed by the inflamed joint. Finally the cartilage is completely destroyed at these parts, and the cancellous tissue of the head of the bone is exposed.

As soon as perforation takes place, the suppuration extends between the cartilage and the bone, the pus being formed from the vascular medullary tissue of the cancellous spaces. The cartilage thus becomes loosened, and is bathed by pus on each side. Its nutrition being cut off it perishes, becomes yellow in colour, and tough and leathery in consistence. Microscopic examination shows that the process is one of sloughing and disintegration. The matrix is opaque and granular, and the cells show no signs of proliferation, but on the contrary have broken down into a mass of fat granules.

At the margins of the cartilages in those parts not exposed to pressure, and in those cases of acute arthritis which terminate without suppuration, the destruction of the cartilages takes place by a process of true ulceration. The cartilages are overlapped at their margins by the granulation tissue formed from the inflamed synovial membrane. On removing this the surface of the cartilage will be seen to be marked by irregular hollows filled with a similar tissue, and in a later stage the cartilaginous tissue will be found to have been destroyed to a greater or less extent. In other parts of the cartilage similar changes may be observed, but they are always most marked in the neighbourhood of the vascular fringes of the synovial membrane. So much is this the case that Aston Key was led to believe that the destruction of the cartilage was directly effected by the development of a fimbriated or fringed vascular network or tissue from the synovial membrane, by which the process of absorption was carried out. The true nature of the changes occurring in ulceration of cartilage was first described by Goodsir, and his observations were confirmed and extended by Redfern and Rainey, who pointed out the fact that cartilage, like other vascular tissues, may undergo changes independent of the prolongation of vessels into it. If a vertical section be made of a piece of articular cartilage in process of ulceration, the changes observed will vary with the acuteness of the process. In some cases the appearances will closely resemble those already described as being met with in ulceration of bone. The surface of the cartilage is seen to be irregularly hollowed out, the hollows being filled with small round cells, having the ordinary appearance of the migrating leucocytes observed in acute inflammations elsewhere; immediately beneath these, the matrix of the unaltered cartilage is cloudy, and the cartilage-cells may be granular, but there is no evidence of proliferation. There is, in fact, nothing to prove that the new cells are derived from the pre-existing cells of the cartilage, and that the process is not exactly analogous to the destruction of bone by cells derived from the vascular medullary tissue, probably by migration from its vessels.

In less acute processes, on the other hand, the destruction of the cartilage is undoubtedly due to changes commencing in its own cells. In a vertical section proceeding from the healthy cartilage to the diseased surface, the following appearances are observed. In from the fifth to the twelfth layer from the surface the cells are seen to be undergoing proliferation; in each capsule two or four cells are found; proceeding towards the diseased surface, the number of cells in each space increases, and they gradually lose the characteristic appearance of cartilage-cells and become indistinguishable from the round cells of granulation tissue. As the cells multiply the spaces containing them necessarily increase at the expense of the surrounding matrix, and at the same time the capsules become more and more indistinct and at last disappear altogether. The matrix near the surface becomes cloudy and granular, and at

last completely disappears before the enlarging cell-spaces, which then coalesce, and thus there is formed on the surface a layer composed entirely of small round cells identical in appearance with those of ordinary granulation tissue. The homogeneous intercellular substance may then soften and the cells may be cast off into the joint as pus-cells; or should the disease tend towards recovery, new vessels may penetrate the groups of cells, proceeding from the nearest vascular tissue, and thus a vascular granulation tissue may be formed, which will take part in the processes of repair subsequently to be described.

In order to distinguish these three processes from each other, we may term the first, necrosis with disintegration; the second, ulceration without proliferation; and the third, ulceration with proliferation.

The *bones*, when exposed by destruction of the cartilages, become affected more or less deeply by the inflammatory process. The changes that occur need no description, as they are identical with those already described in the Chapter on Inflammatory Processes in Bone. They usually assume the form of rarefactive osteitis with suppuration, or simple caries, but if the process be very acute, the inflammatory products in the cancellous spaces may break down into pus before the bony trabeculae have been completely absorbed, and thus portions of the cancellous bone may be cut off from their nutrition and perish, forming sequestra (*caries necrotica*). In other cases the inflammation in the cancellous spaces may spread rapidly, and diffuse osteomyelitis be set up. This is especially prone to happen when the original inflammation in the joint is septic or infective in character.

**CAUSES AND VARIETIES OF ACUTE ARTHRITIS.**—Acute arthritis arises from many different causes, and the course of the disease varies somewhat according to its mode of origin. The following are the chief forms met with in practice:—

**Traumatic Septic Arthritis.**—This arises as a consequence of a penetrating wound of a joint, with admission of impure air and subsequent decomposition of the discharges. It rapidly terminates in suppuration, and in many cases leads to complete destruction of the articulation. It has been fully described under Injuries of Joints (Vol. I., p. 510).

**Acute Infective Arthritis.**—Acute inflammation of one or more joints is a common local effect of more than one general infective process. It is met with in pyæmia arising from wounds, in puerperal fever, scarlet fever, small-pox, and sometimes after typhoid fever. These are probably closely allied if not identical conditions, the general infection taking place from the placental surface in puerperal fever, from the ulcerated throat in scarlet fever, from the pustules in small-pox, and from ulcers in the intestines in typhoid fever, just as, in ordinary pyæmia, it takes place from the unhealthy wound. Pyæmic arthritis begins suddenly, with very acute superficial pain. It differs from many other forms of acute arthritis in the rapid effusion into the joint which occurs at the commencement of the attack. It thus resembles simple acute synovitis in giving rise to a swelling, which at first assumes the outline of the distended synovial membrane. If the patient die at this stage, the joint will be found to have undergone but little change, the synovial membrane is injected, and the fringes swollen, and the cavity of the articulation contains a quantity of thin pus mixed with synovia. If the patient, however, survive more than a few days after the joint has become affected, the inflammation extends to the ligaments, destruction of the cartilages commences, and the case

then runs the ordinary course of acute arthritis. It is sometimes possible to arrest the progress of the inflammation before the destructive changes set in, by early opening, free drainage and antiseptic treatment, but even then considerable thickening and contraction of the capsule usually result, leaving the joint more or less fixed. If the joint be opened without sufficient drainage and without antiseptic treatment, decomposition of the pus in the cavity takes place, and the ordinary results of septic arthritis follow. The exact process by which the joint becomes infected, and what it is that determines the particular joint or joints which are attacked, is not certainly known. The pus contained in the articulation in all forms of infective arthritis is very irritating and contains micrococci in large numbers. (See also Pyæmia, Vol. I., p. 979.)

After scarlet fever it is not uncommon for the patient to suffer from slight swelling and pain in the joints resembling rheumatism. This "scarlatinal rheumatism" subsides without suppuration, and is probably distinct from the pyæmic affection just described.

Acute arthritis may also occur as a complication of gonorrhœa, but this is rare. The milder forms of inflammation of the joints, included under the term "gonorrhœal rheumatism," will be described in the Chapter on Gonorrhœa. When the affection assumes a destructive form it is probably due to pyæmic infection.

**Acute Arthritis from Exposure to Cold. Acute Rheumatic Arthritis.—**

This is a somewhat rare affection. After exposure to cold, especially from sleeping in the open air after being heated by violent exertion, the patient is seized suddenly with acute febrile symptoms, sometimes preceded by a rigor. At the same time swelling, with intense pain, commences in one joint, most commonly the knee. The symptoms at first so closely resemble an attack of acute rheumatism that these cases in hospital practice are commonly first admitted into the medical wards and subsequently transferred to the surgical. The distinction from acute rheumatism is made by observing the following points: the skin is hot and dry, the profuse sweating of rheumatic fever being absent; the affection remains limited to the single joint attacked, and the local symptoms are more severe than in ordinary rheumatism. The ligaments are early implicated, and there is little recognizable effusion into the joint; the pain is most agonizing and is of the character already described as occurring in acute arthritis. Pus may form in the joint in a few days from the commencement of the attack, but under proper treatment, the symptoms usually subside gradually, and the patient slowly recovers, after weeks or months, with the joint always stiffened, and usually firmly ankylosed, sometimes even by bone. The exact cause of the disease is not certain; from its sudden invasion, and its arising from exposure to cold, it has been

Fig. 540.—Interior of Knee disorganized by Acute Pyæmic Inflammation.

termed rheumatic, but the evidence of its being actually related to rheumatism is not clear. Volkmann described it under the name of Croupous Arthromeningitis, and states that it is characterized by an incoagulable exudation both into the synovial cavity and the soft structures forming the joint. It seems most probable that the disease results from infection of the joint by the organisms of suppuration, which reach it from the blood stream. It would thus be closely allied to acute necrosis, and it will be observed that the mode of onset and the character of the functional disturbance are very similar in the two cases.

**Acute Arthritis secondary to Disease of the Bones.**—The diseases of the bones being in most cases tuberculous in nature, these, when they extend to a neighbouring articulation most commonly lead to disease of a joint of a similar nature. The only exception to this rule is the abscess in the head of a long bone. This may perforate the cartilage, and its contents to enter the joint, and acute arthritis, ending rapidly in suppuration, may be set up. If the cavity has already been opened externally a suppurative arthritis containing decomposing pus, septic arthritis, the most acute form always follows.

Fig. 541.—a, Caries at Head of Tibia.  
b, Perforation of Cartilage.

The perforation of the cartilage in these cases is the effect of a process of ulceration identical in character with that already described as occurring in acute arthritis commencing at the articular surface of the cartilage. The perforation of the cartilage in these cases is the effect of a process of ulceration identical in character with that already described as occurring in acute arthritis commencing at the articular surface of the cartilage.

Acute inflammatory processes extending from the bone to the joint always set up acute arthritis. A suppurative periostitis or osteomyelitis of the shaft (Acute Necrosis, p. 277),

stops at the epiphyses, and consequently seldom causes disease of the neighbouring joints. Exceptional cases are, however, met with in which the articulations become affected. In these there is at first abundant exudation into the cavity of the synovial membrane; this rapidly becomes purulent and destruction of the cartilages and softening of the ligaments follow.

Acute osteomyelitis attacking the growing bone in the epiphysis and terminating in its necrosis, or, as it is termed, *acute epiphysitis*, is an uncommon cause of acute arthritis in young subjects. The causes of the affection are not always evident; sometimes it is attributed to injury. On examining a joint affected in this way, the appearances already described as characteristic of acute arthritis with ulceration of the cartilages are met with. On making a section of the epiphysis in which the disease started, the necrotic material contained in it will often be found forming a sequestrum bathed in a purulent cavity in which it lies communicating with the joint by an ulceration through the cartilage. In other cases the epiphysis may be separated from the shaft. Acute epiphysitis is probably in most cases an infective process closely allied to acute infective periostitis and osteomyelitis.

**Syphilitic Epiphysitis** and its effects on the joints have already been described (Vol. I., p. 1170).

**Acute Arthritis from Diseases of the Soft Parts external to the Joint.**—Abscesses arising from any cause in immediate contact with a joint may burst into its cavity. When this happens, acute arthritis with destruction of the articulation invariably follows. This accident may occur in acute inflammation and suppuration of the bursæ in the neighbourhood of a joint. In phlegmonous erysipelas the joints are occasionally opened where the ligaments are in close contact with the subcutaneous tissue.

**Acute Arthritis of Infants.**—Under this name, T. Smith has described a form of acute arthritis, unconnected with syphilis or injury, not uncommonly met with in very young children. It is sudden in onset, and runs a rapid course, ending in suppuration. It is most common in the knee, hip, and shoulder. The first symptom is restricted movement with pain, rapidly followed by swelling, and the formation of pus. In some cases two or three joints are affected. If the abscess is opened early, recovery may take place; ankylosis rarely results, but more commonly a weak movable joint is left. The disease is fatal in a considerable proportion of cases. In the 21 cases recorded by T. Smith, the ages of the patients were as follows: 8 under 1 month, 4 under 2, 7 between 2 and 6, and 3 over 6 months. The *post-mortem* examination of the fatal cases showed rapid loss of substance in the articular end of one of the long bones entering into the joint. Acute Arthritis of Infants does not seem to be a separate disease. Some of the recorded cases were probably pyæmic, arising in very young infants from infection from the umbilical cord; others were instances of acute epiphysitis occurring in young children.

**Senile Acute Arthritis.**—A form of acute arthritis is occasionally, but very rarely met with, occurring independently of any external cause, but apparently due chiefly to simple loss of vitality in old persons of feeble constitution. I have seen it in the joints of the foot, the ankle, and in the sterno-clavicular articulation. It resembles in this respect that form of senile necrosis of bones described at p. 288. In senile arthritis the pain is very acute, the enlargement of the joints considerable, the wasting of muscle rapid and great. The constitutional disturbance is proportionately severe. The joint that it most frequently affects is the knee. I have seen it also in the wrist. This form of arthritis must not be confounded with the dry rheumatic arthritis of old people. It differs from this form of the disease in the acuteness of its local symptoms and the severity of the constitutional disturbance. It is often mistaken in the first instance for gout; but the rapidity of the process, the formation of pus within and around the joint, the necrosis of the contiguous bones, and the separation of the articular cartilages, all indicate the different nature of this affection. The disease is incurable, and usually terminates fatally.

On examining the joint after removal, the cartilages will be found to be ulcerated, the synovial membrane softened, swollen and injected; the ligaments softened, and the articular ends of the bones congested.

**Repair.**—Should the patient recover from acute arthritis without removal of the joint by amputation or excision, the process of repair will vary with the extent of the mischief done before the arrest of the disease. The inflamed ligaments seldom recover their normal condition. The inflammatory products

with which they are infiltrated are partly absorbed, and partly developed into dense fibrous tissue. This process is accompanied frequently by some contraction, so that the natural mobility of the joint is more or less interfered with. Should the position of the joint during the attack have led to relaxation of any ligament, as, for instance, of the ilio-femoral from flexion of the hip, the ligament becomes shortened as the joint recovers, so that the position assumed during the acute stage becomes a fixed one.

The inflamed surfaces of the synovial membrane which have lost their endothelial covering and become covered with granulation tissue, adhere to each other wherever they are in contact, and thus the synovial pouches become obliterated. If the cartilages have been but very superficially ulcerated, they may again become smooth without the formation of adhesions between the opposed surfaces. If, however, the destruction has gone on to the extent of the formation of granulation tissue on the surface of the cartilages, the opposed granulating surfaces coalesce, the new tissue becomes developed into cicatricial fibrous tissue, and the joint is permanently stiffened. This condition is described as fibrous ankylosis. If the cartilage has been completely destroyed, the opposed granulations on the surfaces of the bones coalesce and develop into bone, and thus osseous ankylosis results. In no circumstances does cartilage when once destroyed become regenerated.

**Treatment.**—In acute arthritis, perfect rest of the articulation is of the first moment. Unless this be secured, no other treatment can be of any avail. The limb should be fixed by some efficient apparatus and slung in a cradle. For the hip or knee, Thomas's splints will be found most useful. But not only is absolute immobility of the joint imperatively required as the first means of cure, but slight extension of the limb is almost of equal importance, with the view of removing the pain and preventing the destructive disorganization of the articulation and consequent ankylosis, which result partly from the pressure of one inflamed articular surface against the other by the tonic contraction of the muscles of the limb, and partly from the spasms which occur when the patient falls asleep. The pain, more especially that which results from spasmodic action of the muscles of the limb, is not relieved entirely by simple rest; but it is usually at once removed by means of a weight extension attached to the lower part of the limb. This is particularly the case in inflammations of the hip and knee joints. The weight should be proportioned to the age of the patient. Its use will often at once relieve pain, and enable the sufferer to obtain sleep. Fomentations and ordinary soothing applications, such as a paint composed of equal parts of extract of belladonna and glycerine, may be combined with these means. In the acute stage of the disease, small doses of opium may be useful, and at the same time the patient must be confined to liquid food without stimulants. Leeches applied freely to the joint frequently relieve the pain and diminish the acuteness of the symptoms.

Should these means be successful in arresting the progress of the disease before suppuration takes place, the inflammation often continues in a *subacute* form, and some modification must then be made in the treatment. In this condition, perfect rest is equally imperative as in the acute stage, and may be secured in the same way. At the same time the joint may be repeatedly blistered; but in many instances most benefit will be derived from the application of the actual cautery. This agent, when properly applied, yields

much more certain and successful results than any other form of counter-irritation with which I am acquainted. The patient having been anæsthetized, a cauterizing iron, heated to a black-red heat, should be rapidly drawn over the diseased articulation in a series of parallel lines, across which an equal number of cross-bars are again drawn, without destroying the whole thickness of the true skin. A good deal of inflammation is thus set up, followed by slight suppuration. When this has subsided, the application of the cauterity may, if necessary, be repeated; in this way, the deep gnawing pain will usually be removed, and suppuration of the joint may be averted. For counter-irritants to be of any use, they must be employed before suppuration has set in; it is only torturing the patient unnecessarily to have recourse to these agents when once pus has formed in the articulation. In order that full benefit should be derived from this plan of treatment, it must be persevered in steadily for a considerable length of time. The diet must consist chiefly of liquid nourishment during the acute febrile stage, but good food and stimulants will become necessary in proportion to the increase of the debility. As the inflammation about the joint subsides, a tonic plan of treatment should be adopted.

During the subacute stage, if it be thought necessary to apply counter-irritation, absolute rest of the joints of the lower limb may be obtained, without confining the patient to bed, by the use of Thomas's hip or knee splint. (See Diseases of the Hip and Knee.) If it be thought unnecessary to apply any counter-irritation, the inflamed joint may be efficiently steadied by the application of the starch or plaster bandage, the patient then being allowed to move about on crutches or in a chair. In disease of the joints of the foot, the patient may walk with the bent knee resting on a wooden pin leg.

With respect to the local treatment of the inflamed joint in the later stages of the disease when it has assumed a *chronic* form, it may be stated generally that so long as it is tender on pressure applied perpendicularly or laterally, so long as there is any loosening of the ligaments, or pain induced by movement, it must be kept absolutely at rest in splints, or by a starch or plaster bandage. During this period great care must be taken to keep the joint in the position which will be most useful to the patient, should it become stiff—the straight one for the knee and hip, and the semiflexed for the elbow. In many cases it may be useful to strap the joint firmly, in the way recommended by Scott. This plan of treatment consists in spreading on pieces of lint the strong mercurial ointment, to every ounce of which a drachm of camphor has been added; strips of soap-plaster spread upon leather are then cut of a proper length and breadth, and the joint is firmly and accurately strapped up, the limb having previously been bandaged as high as the joint that is strapped. This dressing may be left on for a week or two, until it becomes loose or gives rise to irritation; over the whole a starched bandage may be applied. In many cases I have found it advantageous to strap up the joint with a plaster composed of equal parts of the emplastrum ammoniaci cum hydrargyro, and the emplastrum apionis or belladonnæ. These applications not only fix the joint and promote the absorption of the inflammatory products within and around it, but by acting as gentle counter-irritants, remove the remains of the inflammation that may be going on within it. If recovery have left the joint stiffened without being actually ankylosed, the natural movement must be restored by warm bathing, fomentation, friction, and passive motion. Warm water, in any way

applied, is singularly useful in restoring the mobility of stiffened joints. Passive movement must be undertaken with great caution, and not until every trace of active inflammation has passed away. It is better to keep the limb fixed a month or more longer than is absolutely necessary than to begin passive movements a day too soon. The chances of ankylosis are only increased and the chronic inflammation prolonged by abandoning the treatment by perfect rest before the proper time.

Should the treatment fail to prevent suppuration, the prognosis becomes far more unfavourable, especially when large joints, such as the knee or hip, are affected; so, likewise, when the articular ends of the long bones are diseased, it is seldom that the joint can recover itself, as caries or necrosis is complicating the arthritis and keeping it up. When the articulation is very sinuous, as in the carpus, or when a number of small joints communicate with one another, if not directly by synovial membrane, at all events indirectly through the medium of ligament and of fibrous tissue, as in the tarsus, a cure can rarely be obtained. As soon as the presence of pus is recognized, steps must be taken to let it out completely, and to drain the cavity thoroughly. It is important that this should be done if possible before the capsule gives way and the pus becomes diffused in the surrounding parts.

When distinct fluctuation is felt and the cavity of the articulation is evidently full of fluid, if there be any doubt as to its nature, the joint should be punctured with the aspirator. If the fluid removed is thin serous pus mixed with synovia, the fomentations and other local means of treatment may be continued, and aspiration repeated if the joint fills again. If thick pus is withdrawn, an opening should be made at once and the cavity drained. If the skin is reddened at one part, under which fluctuation is very distinct, the presence of pus is certain, and aspiration will be of little use.

An abscess in a joint should be freely opened by one or two lateral incisions extending fairly into the synovial cavity, so as to afford a free exit for the pus. The practice of making free incisions into a suppurating joint, as advocated by Gay, was a great improvement on the former method of merely puncturing. The small aperture that was formerly made without any antiseptic precaution admitted air, in consequence of which the pus became offensive and irritating, and, being unable to escape freely, gave rise not only to much local mischief but to severe septic fever. By laying the joint open freely, even when a special antiseptic treatment was adopted, much of this was prevented; and pus was given freely to the pus through one or two incisions extending the whole length of the articulation; the septic poisoning from pent-up and putrid matter was prevented, and in many cases healthy granulations sprang up in the cavity and recovery took place with an ankylosed joint. The chances of this successful termination are very greatly increased by the adoption of an efficient method of antiseptic dressing. The irregular cavity of a joint is difficult to drain perfectly even with the freest incisions, and consequently it is of great importance that such fluid as remains behind should not be allowed to decompose. By the combined use of antiseptic drainage and rest, excellent results are obtained, and excision of the joint or amputation of the limb is usually avoided. It is more especially in the knee, elbow, and hip that this practice has yielded such good results. In some cases, even when the joint has been perfectly loose and grating, by perseverance in this treatment a good and useful limb may be left. Should decomposition

place, profuse discharge followed by hectic or chronic septic poisoning comes on, and pyæmia is not unfrequently developed; if the patient escape these dangers the joint may become useless or cumbersome, and its removal by amputation or excision must be practised. When an attempt is made to save the joint after suppuration has taken place, very special attention will be required, in consequence of the softening of the ligaments, to prevent displacement of the osseous surfaces either laterally or antero-posteriorly; this may be produced partly by the weight of the limb and partly by the traction of the muscles. Any neglect of proper precautions in the more minute details of the application and adjustment of proper apparatus may be followed by a very considerable amount of deformity. Should the joint already have assumed a faulty position, in consequence of the Surgeon neglecting to support it properly in splints in the early acute stage, the patient may be anæsthetized, and the malposition of the limb gently corrected.

With regard to the treatment of the special forms of acute arthritis, little need be said. That of *Acute Septic Arthritis* from a wound has already been described. In *Pyæmic Arthritis*, most commonly little can be done owing to the constitutional condition of the patient, but should there be no visceral complications a cure not unfrequently results after free antiseptic incision, drainage, and rest. Ankylosis almost invariably ensues. In *Acute "Rheumatic" Arthritis*, perfect rest, leeches, and hot fomentations must be tried. Should suppuration take place, free incisions may be successful in saving the joint. In *Acute Arthritis secondary to disease of the bones*, the results of treatment are not very satisfactory. An attempt may be made to save the joint by removing sequestra and treating the carious surface as described in the Chapter on Disease of Bones, but it often fails, and amputation or excision becomes necessary. In *Acute Arthritis of Infants*, the joint must be laid freely open as soon as pus forms, and by this means the limb can usually be saved. In *Senile Arthritis*, the treatment must be conducted on ordinary principles of rest, fomentations, opiates, and supports. But at last, in order to prevent destruction of life by pain and exhaustion, the question of amputation will arise; and, serious as this may be in old people, it will be the only alternative and chance of escape from a painful death.

#### TUBERCULOUS DISEASE OF JOINTS.

This important group of joint affections has long been studied under the various names of "**Strumous Arthritis**," "**White Swelling**" (Wiseman), "**Pulpy degeneration of the synovial membrane**" (Brodie), "**Fungous inflammation of joints**," etc. During recent years, however, the observations of numberless workers both in this country and abroad have shown incontestably, that all these affections, although differing widely in their clinical manifestations, are tuberculous in nature.

It is impossible here to consider in any detail the large amount of evidence, both clinical and pathological, upon which this view is based. It is, indeed, in most respects, similar to that which has already been mentioned in connexion with tuberculous diseases of bones (p. 267): thus the histological examination of the diseased tissues, the presence of the tubercle bacillus, and the frequent association of these chronic joint affections with tuberculous lesions elsewhere, point with certainty to their true nature.

In 72 cases examined by König tuberculous tissue was found in 67, and in the remaining five the material for examination was deficient, so that no conclusion could be arrived at as to its presence. Croft and Greenfield and other observers agree as to the constancy of the presence of tubercle.

The statistics of white swelling show moreover that in a very large proportion of fatal cases death takes place from general tuberculosis. Albrecht has published some statistics, in which it is shown that, out of 135 fatal cases, in 64 death occurred from tuberculosis. If further proof be needed, the characteristic lesions have been produced by the injection of tuberculous material or of pure cultivations of the tubercle bacillus into the joint-cavities of animals, and in a few recorded cases by accidental inoculation of a joint in the human subject. Of this last occurrence Pfeiffer's well-known case is a good example. A veterinary surgeon wounded the joint of his thumb in dissecting a tuberculous cow. The puncture healed, but soon the joint became enlarged, and the patient died of phthisis eighteen months after the injury. Examination of the joint showed well-marked destructive changes; whilst the diseased tissues presented the characteristic lesions of tubercle and contained tubercle bacilli in abundance. It will be convenient to consider first the anatomical changes met with in the chief varieties of tuberculous joint disease and then to describe the clinical features presented by the disease in its different stages.

**Pathological Anatomy.**—If those unusual cases are excluded in which tubercle of a joint occurs secondarily to disease of neighbouring bursæ or tendon sheaths, two chief varieties need consideration—first, primary tuberculosis of the synovial membrane, and secondly, primary tuberculosis of the articular extremity of a bone with secondary invasion of the joint-cavity. Although in the later stages the disease tends to affect all the articular structures, so that it may be impossible to determine its exact starting-point, yet the division is a practical one, and the two varieties will be described separately.

**Primary Tubercle of the Synovial Membrane.**—The pathological changes have been very accurately described by Billroth, König, Cheyne and others. In the earliest stages that have been observed, the synovial fringes are swollen and the membrane is generally thicker than natural, and hyperæmic. There is, as a rule, no increase of secretion, but the synovia is often slightly turbid. As the disease advances, the synovial membrane becomes thicker and more vascular, its natural smooth surface is lost, and soft spongy granulations spring up upon it, the deeper parts becoming dense and fibrous. This change is especially marked in the synovial fringes. These form soft masses of granulation tissue which fill up the angles between the articular surfaces and gradually creep over the cartilages. In some instances grey granulations can be seen scattered through the granulation tissue. Where two granulating synovial surfaces are in contact, as in the pouches of the knee-joint, they coalesce, and thus the cavity of the joint gradually becomes obliterated. It is in consequence of this limitation of the disease to the synovial membrane in the early stages, that the swelling of the joint, observed clinically, takes the form of the distended articular cavity, as in simple synovitis with effusion. As the disease advances, the chronic inflammation extends to the ligaments and capsule, which become infiltrated with the inflammatory products, and swollen and lardaceous in appearance; and later on the areolar tissue surrounding the joint is similarly affected. It is owing to this that the swollen

joint loses the form of the distended synovial membrane which characterized the earlier stages, and becomes rounded or oval. Simultaneously with the affection of the ligaments, the growth of the granulation tissue within the joint continues until the synovial membrane is replaced by a soft pulpy mass of granulation tissue from half an inch to nearly an inch in thickness. The growth gradually spreads over the cartilage, covering it like a veil. If an attempt be made to remove this it will be found that the advancing edge can be raised with the handle of the scalpel for about one-eighth of an inch, beyond which it will be adherent to the cartilage. The advance of the granulation tissue over the cartilage is compared by Billroth to ivy creeping over a wall, and becoming gradually attached by its roots. If the granulation tissue be scraped away, it will be seen that it is growing into and pitting the surface of the cartilage, which is thus at last completely perforated. In this way the granulation tissue reaches its deep surface, and extending beneath it may lead to loosening and complete detachment of considerable portions.

After the perforation of the cartilage the subjacent bone becomes affected. Here the process assumes the form of rarefying osteitis with exuberant growth of granulation tissue (Superficial Fungating Caries, p. 267); the destructive process may extend to a varying depth into the cancellous tissue of the articular end of the bone. The periosteum usually shares in the disease, the inflammation assuming the osteoplastic form, and leading to the deposit of irregular masses of bone on the articular ends, chiefly in the immediate neighbourhood of the joint. At this stage no articular cavity remains; the joint is represented merely by the articular ends of the bone more or less extensively denuded of cartilage, embedded in a soft pulpy mass of granulation tissue, surrounded by the infiltrated and softened ligaments. When the granulation tissue reaches the thickness of from a quarter to half an inch, caseation occurs, and it is from the appearance of the mass of tuberculous granulation tissue that the disease received its name of "pulpy degeneration of the synovial membrane." The soft pulpy tissue is pink in colour, marked by yellowish patches of fatty degeneration and brown areas from old hæmorrhages. The fatty degeneration is followed sooner or later by softening, and thus a chronic abscess with flocculent curdy contents is formed. This frequently occurs in one or more local centres, without implicating the whole mass of granulation tissue. Thus, in the knee, it frequently occurs in the synovial pouches above the joint.

Although the above description indicates the usual series of changes resulting from tuberculous disease of the synovial membrane, several modifications are recognizable which are of considerable practical interest. Watson Cheyne recognizes four distinct forms of tuberculous disease of synovial membrane. First, that resulting in diffuse thickening of the membrane. This is the form above described, and is by far the most common. Secondly, limited thickening of the synovial membrane. This is an uncommon form described by König and Riedel, and has been met with chiefly in the knee-joint. Distinct nodular or polypoid growths may form in the synovial membrane. These outgrowths consist of vascular connective tissue and granulation tissue and may be associated with considerable effusion into the joint. Thirdly, acute *miliary* tuberculosis of the synovial membrane. This form, which has been described by König, is occasionally met with in general tuberculosis, and is not necessarily associated with any clinical evidence of joint-disease. Fourthly,

tuberculous hydrops and empyema. *Tuberculous hydrops* has been so called by König on account of the extensive effusion into the joint which occurs. He states that it may be caused by diffuse tuberculosis of the synovial membrane with or without marked thickening. When the membrane is thickened, it is due, in some cases, to the deposit of fibrinous layers upon it, especially on the fringes, which may become villous or even polypoid in appearance. In these cases loose bodies may be present in the joint. In most instances tuberculous hydrarthrosis ends sooner or later in the more usual forms of the disease. It occurs most commonly in young adults, very rarely in children. In *tuberculous empyema* of a joint the cavity is filled with curdy pus before the synovial membrane is obviously thickened. According to Cheyne, this form occurs especially in old people.

**Primary Tubercle of Bone.**—Having briefly considered the most impor-

Fig. 542.—Bones from a case of tuberculous disease of the knee-joint showing large wedge-shaped sequestra in the inner condyle of the femur and the corresponding surface of the tibia.

tant changes which take place in a joint as the result of tuberculous disease of the synovial membrane, it remains to describe the changes resulting from secondary infection of the joint from a primary deposit of tubercle in one of the bones entering into its formation. The changes in the bone itself have already been described (p. 265), and consist in a destructive inflammation of the cancellous tissue around a tuberculous deposit. Not uncommonly the carious cavity contains a more or less wedge-shaped sequestrum, the broader end of which may lie immediately beneath the articular cartilage (Fig. 542). When the disease has reached the deep surface of the cartilage, this is gradually destroyed from below in a manner similar to that in which it is eroded from the superficial surface in primary disease of the synovial membrane.

When the cartilage is completely perforated the tuberculous tissue extends into the joint-cavity (see Fungating Caries, p. 267), and infection of the synovial membrane occurs, resulting in changes similar to those due to primary deposit in the membrane itself. The earliest stage of infection of the joint was well illustrated in a case recently treated in University College Hospital. The patella was the seat of an extensive caseous deposit, and on opening the knee-joint, the synovial membrane in its anterior part was found swollen and injected, whilst grey granulations could be recognized scattered over it. In some cases adhesions occur in the joint before the cartilage is actually perforated, so that only a limited part of the synovial membrane may become tuberculous.

The exact position of the primary focus which serves as the starting-point of the disease varies in different cases. It may be deeply seated in the cancellous tissue of the articular extremity, immediately beneath the articular cartilage. In many cases, however, it is situated in the vascular growing bone between the epiphysis and the shaft; it may then infect the joint by perforating the cartilage, or it may extend to the surface of the bone at or within the line of the attachment of the capsule, and thus reach the joint by a different route.

It occasionally happens, especially in the shoulder, that the disease of the bone assumes the form of dry caries (p. 257), and thus extensive destruction may occur without any evidences of suppuration, and the true nature of the case may consequently be obscure.

The proportion of cases in which the synovial membrane is primarily affected has been differently estimated by different pathologists. König is of opinion that primary synovial disease does not form more than a quarter of all cases. The frequency with which it occurs varies in different joints: thus it is more common in the knee than in the hip or elbow. Clinically it is, as a rule, impossible to distinguish accurately one form of the disease from the other.

On microscopic examination, the diseased structures present the following appearances: The ligaments show the ordinary changes observed in inflamed fibrous tissue. The fibres are separated from each other by inflammatory products, composed chiefly of small round cells. When the process is very chronic, new fibroid tissue may also be found. The cartilages show changes similar to those already described in acute arthritis. Before suppuration has taken place, ulceration both without and with evident proliferation may be present (see p. 335). The destructive changes may be observed on either surface, according as the disease commences in the synovial membrane or the bone. In the later stages, after perforation of the cartilage, both surfaces may be similarly affected. After suppuration has taken place, necrosis of cartilage with disintegration (p. 335) may also be met with. The bones present the appearances already described as being met with in tuberculous caries (p. 282). The chief interest attaches, however, to the microscopical appearances of the pulpy granulation tissue which has replaced the synovial membrane and fills the cavity of the joint. The structure of this tissue has been made the subject of investigation by Köster, König, Volkmann, Hueter, and others in Germany, and by Croft, Greenfield, Cheyne and others in this country.

The essential part of the pulpy granulation tissue is made up of the elements which are characteristic of tubercle elsewhere, and these may assume the nodular

or infiltrating form (see Vol. I., p. 1086). The most important conditions met with are thus described by Watson Cheyne. In the first and most common form the thickened membrane is composed of two layers: an inner one, soft, often caseating and consisting of tuberculous tissue; and an outer layer composed of swollen vascular fibrous tissue. In another form the tubercle is deposited in the substance of the membrane, which forms a single tough layer, in which caseation may occur and chronic abscesses be formed. Lastly, the synovial membrane may be converted into a thick mass of swollen fibrous tissue, in which the tubercles are few in number, and in parts entirely absent. Cheyne finds that the first variety is usually due to secondary infection of synovial membrane from an osseous deposit. Here the tuberculous tissue is superficial and can be removed by scraping, but in the other forms the dense fibrous tissue can be removed completely only by dissection.

Tuberculous joint diseases not unfrequently follow sprains and other slight injuries. In such cases it is probable that the damage to the tissues thus produced renders them favourable to the growth of the tubercle bacillus, which reaches them by the blood stream, in some cases no doubt from a pre-existing caseous focus elsewhere.

**Symptoms.**—The disease in many cases supervenes slowly on some slight injury, but in others no definite cause can be assigned for its appearance, and the exact date of its commencement is often difficult to ascertain. It may commence as the chronic form of synovitis (see Chronic Synovitis, p. 328) in a strumous subject, assuming its peculiar characters at a later period. It is most frequently met with in children and females. The disease begins gradually with some pain and stiffness in the joint, causing a slight limp in walking if a joint in the lower limb is affected. The pain is increased after any unusual exertion, and may then be severe enough to oblige the patient to rest for a day or two, when the symptoms usually subside. If the joint be examined during this stage, there will usually be found some slight limitation of movement, complete extension or flexion causing pain. If the joint be superficial, as the knee, elbow, or ankle, it will be seen to be swollen. The natural hollows are less clearly marked than in health, or even completely obliterated. The swelling at this stage takes the form of the distended synovial cavity, as in synovitis with effusion, but it does not give the same sense of fluctuation, being semi-elastic and pulpy. Sometimes, however, it is so soft that it is readily mistaken for fluid, even by the practised hand. In the knee it may be distinguished by observing that, though the patella is raised, it cannot be pushed down with a distinct concussion on the femur, as in synovitis with effusion. As the disease advances the joint becomes more enlarged, and as the ligaments become implicated the swelling loses the outline of the synovial membrane and assumes a more rounded or fusiform outline, the bony prominences being effaced by a uniform, doughy, semi-elastic or pulpy swelling. The integuments covering it preserve their white colour; hence the name "white swelling" which has been applied to the disease. Usually but little pain is felt when the limb is at rest, but motion becomes more and more painful, till it is no longer possible to use the limb. The position assumed by the limb at this time is that in which the patient has most ease, viz. that of semi-flexion, and with this there is a considerable degree of stiffness and rigidity. In this stage the inflammation commonly extends to the periosteum covering the articular ends, which become slightly

enlarged by deposit of new bone. The degree to which the articular ends are enlarged is very difficult to estimate, as they are usually obscured by the swelling of the surrounding soft parts, and in consequence of the wasting of the muscles, the articulation appears more swollen than it really is. If the disease continues to progress, starting of the limb sets in at night. These starting pains occur at the moment when the involuntary contraction of the muscles which fix the inflamed joint suddenly relaxes. They are especially severe when erosion of the cartilage has taken place, but they also occur in the earlier stages. After these symptoms have persisted for a varying time the swelling becomes more prominent at one part, fluctuation becomes manifest, and the skin covering the prominent part gradually assumes a dusky red tint. Finally, if not anticipated by surgical interference, the abscess bursts, discharging unhealthy pus mixed with curdy masses. Before this takes place it may reach a considerable size and burrow for some distance from the articulation. The abscess does not necessarily occupy the whole cavity of the joint, for, as has been pointed out in describing the pathology of the disease, no cavity may exist by the time the abscess forms, the whole articular space being filled up with a mass of tuberculous granulation tissue, in one part only of which the suppuration may have taken place. In other cases the abscess may form outside the joint, superficially to the ligaments. After the abscess has burst, its cavity may gradually contract and heal, but more commonly a sinuous track is left leading to the diseased joint. In other cases, especially if the abscess but incompletely empties itself, decomposition of the discharges sets in, the granulation tissue filling the cavity of the joint may rapidly break down, and the disease then assumes the form of acute septic arthritis (Vol. I., p. 510), with severe pain and rapid destruction of such cartilage as may have remained undestroyed at the time the chronic abscess burst. The limb swells and becomes œdematous, and other abscesses form around the joint. The ligaments become further softened, grating can be felt, and the articular surfaces become displaced.

The local phenomena of white swelling may thus be divided into three stages: first, that in which the disease is apparently limited chiefly to the synovial membrane and the swelling assumes the form of the synovial cavity; secondly, that in which the ligaments, cartilages, and articular ends of the bone become implicated, and the swelling becomes oval or rounded; and thirdly, the stage of suppuration.

The variety of tuberculous disease which has been called by König "tuberculous dropsy" is characterized by very chronic effusion, usually moderate in amount and refractory to treatment, or if any improvement takes place, speedily relapsing. The movements of the joint are limited but not painful. There is usually thickening of the synovial membrane, which may readily be felt if the distension is not great. In some cases, in the knees, König has felt a distinct fibroid mass resembling a tumour at the lateral reflexion of the synovial membrane.

The constitutional symptoms vary in the different stages of the disease. The general health does not appear to suffer in the first stage beyond some slight febrile disturbance during exacerbations from over-exertion of the joint. In the second stage also, the general health is but slightly impaired, except from want of exercise, and at the later period from want of rest if nocturnal startings set in. In the third stage there is progressive loss of strength.

Even when the suppuration is very chronic there is usually some slight evening elevation of temperature, seldom, however, exceeding 101° F. After the abscess has burst, the constitutional symptoms become more severe, hectic may speedily set in, and tuberculous disease of other organs, such as the lungs, may carry off the patient.

**Terminations.**—Tuberculous disease of joints resembles tubercle elsewhere in its course and terminations. It may end in recovery by the development of fibrous tissue from the vascular granulation tissue surrounding the tubercle, the actual nodules withering and remaining harmlessly embedded in scarlike fibroid tissue, or the tuberculous tissue may caseate and soften, giving rise to the formation of a chronic abscess, the tubercle being thus in some cases eliminated from the body. Calcification rarely if ever occurs in tuberculous disease of the synovial membrane. The course taken by the disease depends partly on the constitutional state of the patient, partly on the hygienic conditions by which he is surrounded, and partly on the treatment he receives. Recovery in most cases may be hoped for if the constitution is generally sound, if the patient is well fed, well clothed, and can spend a great part of the day in the open air in a healthy place, and above all, if such treatment is adopted as to give perfect rest to the diseased joint. On the other hand, in extremely scrofulous subjects the disease will often progress to destruction of the joint in spite of favourable surroundings and good treatment, and the same result frequently follows amongst the poor of large cities owing to the unfavourable hygienic conditions in which they are placed. Lastly, unless by proper treatment perfect and prolonged rest is given to the diseased joint there is no hope of recovery, however favourable the other conditions may be.

Imperfect recovery, with a stiffened and deformed limb, may occur after complete destruction of the articulation, especially when as the result of dislocation the diseased surfaces are no longer exposed to the irritation caused by the friction of one against the other. This is not uncommon in the hip. In a considerable proportion of cases the patient dies of tuberculous disease of the lungs or general tuberculosis before recovery of the joint has taken place.

**Duration.**—Tuberculous disease of joints usually runs a very chronic course. Recovery can rarely be hoped for under six months, and most commonly treatment has to be maintained for twelve months, and sometimes for even two or three years.

**Treatment.**—In the treatment of tuberculous diseases of joints every effort must be made to improve the general health. We must therefore follow the rules of *constitutional treatment* laid down in Chapter XXXV., Vol. I., without which the local treatment about to be described will often prove ineffectual. Reference has already been made to the use of tuberculin in Vol. I., p. 1101.

In the *local treatment* in the early stage, our first object is to arrest the progress of the disease, and, if possible, to prevent the occurrence of suppuration. The one essential condition for this is that *the joint be put at perfect rest*, without which all other treatment will be futile. By perfect rest we mean that the joint shall be so fixed by some suitable apparatus that the slightest movement of the articular surfaces upon each other is impossible, and, if it be in the lower extremity, that the patient shall bear no weight upon the affected limb. In almost all cases it is necessary that this absolute rest should be

maintained for at least six months, and in a very large proportion it must be prolonged for a year or more. The period of rest must not be shortened, for fear of causing stiffness of the joint. Imperfect rest from defective apparatus, by prolonging the disease, is a much more frequent cause of permanent impairment of function than perfect rest however long maintained. So long as there is any tenderness, pain, or marked swelling, rest must be continued. It is better to err, if at all, on the side of too prolonged rest, as premature removal of the apparatus will certainly be followed by a relapse of the disease. As in most cases it is uncertain what degree of stiffness will be left after recovery, the joint must be fixed in that position which will leave the most useful limb should ankylosis occur. Thus the knee and hip must be fixed in the extended position, and the elbow flexed to a right angle. The apparatus used will necessarily vary with the joint affected. If it be the hip or knee that is diseased, the best splints are those invented by H. O. Thomas, of Liverpool, which will be described in a subsequent chapter. If the ankle is diseased, the joint should be fixed in a plaster-of-Paris bandage, and the patient may be allowed to move about, kneeling on a "pin leg," with a trough to support the limb below the knee. In the upper limb the affected joint may be fixed by leather or gutta-percha splints or by the plaster or starched bandage.

Under certain circumstances the "*extension treatment*" may advantageously be combined with fixation of the joint. The object of the extension is to overcome the tonic contraction of the muscles by which the articular surfaces are kept constantly pressing against each other, and not, as some have supposed, to cause actual separation of the surfaces. Cheyne believes that the muscular contractions are most marked when the bones are affected, and that therefore in these cases extension is most useful. As soon as the muscles have become relaxed further extension is useless, and may indeed be harmful by stretching the inflamed ligaments. The extension is best carried out by attaching a weight to the limb on the distal side of the diseased joint by means of a cord running over a pulley. It is most useful in the hip and knee, and a weight of four pounds or less is usually sufficient. When the patient is suffering from an exacerbation of the disease, with acute suffering on the slightest movement and starting pains at night, nothing will give such immediate relief as a well-applied weight extension apparatus. It is especially useful when the joint has become flexed or otherwise displaced, so as to make the immediate application of a rigid apparatus unadvisable. Under the extension treatment the acute symptoms usually subside before long, when an ordinary fixing apparatus may be applied.

As accessories to the essential treatment by rest, *Compression* and *Counter-irritation* have frequently been employed. Compression may be carried out by means of bandages, strapping or splints, but it is very doubtful if it produces any real effect in the early stages of the disease. Counter-irritation by means of repeated blisters was formerly much employed, but the good it does, if any, is not enough to compensate for the pain it occasions. In some cases the actual cautery does seem to be of essential service. The indications for its use are severe starting pains, especially at night, occurring in a case of chronic disease in the adult, without any evidence of suppuration having taken place in the joint. It must be applied as described at p. 341, and is often followed by immediate relief of the symptoms. Leeches are occasionally useful in relieving pain during an acute exacerbation of the disease from want of rest, but they

must be used sparingly if at all. The external application of mercurial preparations, with a view of promoting absorption of the inflammatory product is rarely productive of good, and may be positively injurious from its constitutional effect. To sum up, it may be stated that in the early stages of tuberculous joint disease most Surgeons are at the present time inclined to rely upon perfect rest, with or without extension, as the local treatment, combined with proper attention to the general health.

The expectant treatment is most likely to prove successful in cases in which the disease is limited to the synovial membrane, but it occasionally succeeds even when there is strong evidence of a tuberculous deposit in the bone. In a large number of cases, however, especially among the poorer classes, some form of operative interference will sooner or later be required, and it is a matter of the utmost importance to decide in what cases this is necessary. Although it is impossible to lay down rules which shall include all the conditions indicating operative interference, most Surgeons will agree with Watson Cheyne that it is certainly required under the following circumstances: First, when chronic suppuration has occurred; secondly, in the early stages, when the disease is localized to one part of the synovial membrane or bone; thirdly, in the later stages, when there is a deposit in the bone with general synovial thickening; fourthly, in cases of synovial disease, when expectant treatment has failed to arrest its progress; fifthly, in cases in which a better functional result can be obtained by operation; sixthly, in certain cases when phthisis is present, or when the general condition is such as to make removal of the disease necessary. The operative procedures adopted are four in number: Arthrotomy or Incision, Arthrectomy or Erasion, Excision or Resection, and Amputation. It is needless to say that these should be undertaken with the strictest attention to antiseptic precautions, upon the success of which the result will to a great extent depend.

**Arthrotomy** consists merely in freely opening the joint by one or more incisions, so placed as to injure the neighbouring muscles and tendons as little as possible. The operation is thus performed: The limb must first be thoroughly cleaned with soap and hot water, and afterwards washed with perchloride of mercury solution (1 in 500), or carbolic lotion (1 in 20). It is then made bloodless if possible by Esmarch's bandage. The joint is then freely opened by one or more incisions placed, if possible, at the most dependent part of the articulation, and of sufficient length thoroughly to drain the cavity without necessitating the use of drainage-tubes. The wounds should be held open with blunt hooks, and any pulpy granulation tissue that comes into view should be removed with forceps and scissors. In some cases an oval slice of the diseased membrane may advantageously be taken away. If the incision have been so planned that no important vessel is wounded, the dressing may now be applied before removing the tourniquet. The following dressing has been found to succeed very well in a considerable number of cases at University College Hospital: The wounds are first dusted with iodoform, and then over each a strip of the "green protective" oiled silk dipped in carbolic lotion is applied in order to prevent scabbing. Over this is placed a piece of carbolic gauze wrung out of carbolic lotion (1 in 20), so that there may be a powerful chemical antiseptic next the wound during the period of early discharge. Over this is placed a pad some inches thick of absorbent salicylic or iodoform wool, reaching about a foot on each side of the joint, and secured by a bandage.

applied with moderate firmness. The splint necessary to fix the joint immovably is then applied, the patient is replaced in bed with the limb elevated at a right angle to the body, and the tourniquet is removed. At the end of twenty-four hours, when all fear of oozing is past, the limb may be brought down to the level of the body. If all goes well, the discharge soaks into the wool and dries, and the dressing may often be left untouched for a month or six weeks, at the end of which time the incisions will in most cases have healed. The indications for changing the dressing are pain, elevation of temperature, or the appearance of discharge from under it.

**Arthrectomy or Erasion** was first recommended by Volkmann as a substitute for excision, and was first described in this country by Wright of Manchester, who practised it for tuberculous disease of the knee. In performing arthrectomy the Surgeon aims at the complete removal of the diseased tissues with the least possible damage to the healthy parts. The diseased joint is laid freely open, and the tuberculous synovial membrane is dissected away as completely as possible with a scalpel or scissors and forceps. At the same time carious cavities may be scraped with a sharp spoon. After the operation the same treatment may be adopted as after incision.

**Excision or Resection** consists in the removal of the articular extremity of one or both the bones entering into the formation of the joint. A general consideration of the subject of the excision of joints will be found at the end of this chapter, and the operations will be described in connexion with the individual joints.

**Amputation** is occasionally required as a last resource; but the cases in which it is necessary have greatly diminished in number owing to the improvements in conservative surgery dependent upon the antiseptic treatment of wounds.

Simple incision of tuberculous joints has been largely replaced by partial or complete arthrectomy. The good effect of incision is probably due to a great extent to the relief of tension, as the diseased tissue is not extensively removed. In cases of tuberculous dropsy of a joint with evident thickening of the synovial membrane, König recommends a free incision with removal of a slice of the diseased membrane on each side. The operation in his hands has been attended with satisfactory results, a movable joint being obtained. It must, of course, be performed with the strictest antiseptic precautions.

Amputation on the other hand is likely to be required only when there is extensive disease of the bones and surrounding parts, or when extensive recurrence has followed other operative measures; when albumenoid degeneration of viscera is present; or when the general condition of the patient necessitates removal of the diseased part in such a way as shall require the least amount of reparative power to recover from the operation. In the majority of cases therefore the choice lies between arthrectomy and excision, the relative merits of which, when both are available, will be considered in connexion with the individual joints. In any case the success of the operation must be judged not only by the completeness of the cure of the disease but also by the subsequent utility of the limb.

In cases that recover without operation much *thickening and stiffness of the joint are left*, and measures may be adopted for removing these conditions, and restoring the flexibility of the articulation by frictions with somewhat stimulating and counter-irritant embrocations, and eventually its strength by

douches of sea-water. The swelling and puffiness that are left, together with the weakness dependent on relaxation of the ligaments, are perhaps best remedied by the use of strapping; but pressure should not be applied so long as there is evidence of active inflammation going on in the articulation, which it would certainly increase.

CHRONIC RHEUMATIC ARTHRITIS, RHEUMATOID ARTHRITIS, ARTHRITIS DEFORMANS, OSTEO-ARTHRITIS.

By these terms is meant a chronic disease of the joints of a progressive character—painful, disabling, deforming, and incurable. This disease has long attracted the attention of physicians, and has been described as “rheumatic gout,” “nodosity of joints,” and “deforming arthritis,” or “osteo-arthritis.” But little was really known of its true nature until its pathology was studied by R. Adams and R. W. Smith of Dublin, who accurately described it under the name of “chronic rheumatic arthritis.” More recently, Garrod added much to our knowledge of this disease, and proposed for it the name of “rheumatoid arthritis.” When it gives rise to much distortion of limb and deformity of joint, as often happens when the hands are chronically affected, the name of “arthritis deformans” is given to it.

This disease may attack any joint, and may continue limited to it, or may extend from one to another until most of the larger articulations are involved. It commences usually in the joints of the limbs, and may be confined to them, or it may primarily attack the temporo-maxillary articulations or those of the spinal column. It occurs in both sexes with tolerably equal frequency. But some joints appear to be more liable in one sex than in the other. Thus the hip in the male, and the knee in the female, are more commonly the seats of the malady.

Rheumatoid Arthritis is essentially a disease of middle age; when once it sets in it will continue for an indefinite period, far into old age. It may affect one or two joints symmetrically, especially when it occurs in persons otherwise healthy and past middle life. It is then usually confined to the larger articulations. In other cases it may attack a number of joints, including the smaller articulations, such as those of the fingers. This form is often termed *polyarticular rheumatoid arthritis*, to distinguish it from the more limited or *monarticular* affection. It often leads to great deformity, and may entirely cripple the patient. It is met with sometimes at a comparatively early age, especially in anæmic females.

Rheumatoid Arthritis consists essentially in an organic change of structure in all the various component parts of the affected joint. The starting-point of the disease appears in most cases to be the cartilage. The first change observed is a loss of polish and smoothness, gradually increasing till the surface becomes velvety in appearance. Microscopic examination shows that this change is due to the gradual conversion of the matrix into fibrous tissue, the fibrillæ of which are arranged at right angles to the surface. At the same time multiplication of the cartilage cells takes place, so that the capsules are found to contain an excess of cells, which, however, retain the appearance of cartilage cells. The cartilage so altered is gradually worn away by the friction of the diseased surfaces against each other, until the bone is exposed. When this takes place the exposed bone becomes increased in

density by the formation of new osseous tissue filling up the cancellous spaces. The new tissue may be true bone with lacunæ, but in many cases it is excessively dense in structure, contains a great excess of lime salts, and appears to be formed rather by calcification than by ossification of the medullary tissue of the cancellous spaces. The bony surfaces thus exposed are worn away, and greatly altered in shape by constant friction; at the same time they become highly polished, like ivory or porcelain—eburnated or porcelaneous as it is termed. In spite of the density of the structure thus formed, it is constantly being worn away as long as motion is left in the joint, the next layer of cancellous tissue then undergoing the same change. These destructive processes commence and advance most rapidly in the central parts of the articular surfaces, and while they are in progress outgrowth occurs at the circumference of the cartilage forming in the earlier stages a rounded lip or flange-like projection around the margins of the articular surfaces. Later on irregular cartilaginous outgrowths are formed which ossify, and thus form rounded irregular osteophytes, often reaching a very considerable size, and impeding or completely abolishing the movements of the joint. The osteophytes of rheumatoid arthritis differ essentially from those formed round a carious joint. In form and appearance they have very aptly been compared to the gutterings of a wax-candle, while the osteophytes round a carious joint have the jagged form of stalactites. The fact that the former are developed from cartilage and the latter from granulation tissue forms another distinction between them. New bone may also be formed beneath the periosteum of the adjacent bone; thus when the shoulder is affected the acromion may be irregularly enlarged by bony outgrowths. Occasionally isolated nodules of ossifying cartilage of a flattened form are found in the subserous tissue beneath the synovial membrane. In the early stages the ligaments and synovial membrane show but little change; but as the disease advances, the capsule of the joint becomes greatly thickened. The synovial membrane becomes opaque, and its fringes increased in size. In some cases this enlargement of the fringes is very considerable, the separate papillæ reaching a great size, sometimes even half an inch in length. When this condition is very marked the term *Villous Synovial Membrane* is applied to it. In the free extremities of the enlarged papillæ rounded or flattened nodules of cartilage may be formed. These sometimes become broken from their attachments, and form loose bodies in the joint.

In the earlier stages of rheumatoid arthritis there may be a slight excess of synovia which is turbid, but effusion never forms a marked feature of the disease, and hence the term *dry arthritis* is often applied to it.

A section of the bones entering into the affected joint shows that the cancellous tissue beneath the eburnated surface is more spongy than natural, the spaces being filled with yellow fat. In consequence of this atrophy of the bone, the shape often becomes considerably altered. This is most characteristically seen in the neck of the femur, which becomes shortened and set more at right angles with the shaft than natural.

Suppuration rarely occurs in rheumatoid arthritis. I have seen it only when the disease was developed at an earlier period of life than usual, at from thirty to forty, or when an injury occurred to the affected joint.

**Symptoms.**—The affected joint becomes partially ankylosed; it is swollen, tender, deformed, and useless. It is the seat of constant pain with occasional

exacerbations, often very severe and prolonged. The general health may continue fairly good, though life is rendered miserable by pain and decrepitude. One of the most marked features of the disease is the crackling felt on moving the joint. In the early stages this is soft, but as the cartilages are destroyed and the bones exposed, it becomes gradually harsher till it may almost resemble the crepitus of a broken bone. When the synovial membrane is villous, there is considerable fulness of the joint with a very fine soft crepitation in movement.

The **Causes** of rheumatoid arthritis are for the most part very obscure. Long continued exposure to damp cold, as prolonged residence in a damp house, or on a wet and clayey soil, undoubtedly predisposes to the disease, and in many cases appears to be the direct occasioning cause. The sprain of a joint will in many cases appear to be the local determining cause. It must, however, be remembered that extensive changes may be present in several joints, whilst pain and stiffness are complained of only in one of them which has recently been injured; the injury merely causing an exacerbation of the pre-existing disease. On the other hand there is some reason to think that a series of chronic destructive changes may sometimes be induced in a joint by a slight injury—a true “chronic traumatic arthritis,” which has no real relation with rheumatic arthritis. The essential cause of the disease is indeed unknown. It appears to have no connexion with tubercle, gout, or true rheumatism except in so far as these act as depressing agents. As Garrod truly observes, it is much easier to prove what rheumatoid arthritis is not, than to give the slightest clue to what it is. It is generally supposed to be dependent upon some form of malnutrition of the system, and to be predisposed to by depressing influences, physical or mental. That deficient or perverted innervation may in some manner lead to rheumatoid arthritis is not improbable, the more so when we consider that a somewhat analogous form of joint affection has been described by Charcot as one of the characteristic phenomena of locomotor ataxy.

The **Diagnosis** of rheumatoid arthritis, especially of the polyarticular variety, is usually easy. This may, however, be confounded with gout and chronic rheumatism. As a rule, the absence of effusion or its small amount, the character of the grating and the presence of bony outgrowths, will show the nature of the affection. The monarticular variety must also be distinguished from Charcot's disease, gonorrhoeal rheumatism and senile tuberculous disease. The diagnosis from Charcot's disease will be considered subsequently. Gonorrhoeal rheumatism can usually be distinguished by the age of the patient, the rapid effusion in the early stage, and the tendency to fibrous ankylosis. Tubercle of joints is rare at the age when rheumatoid arthritis is common, and it is only in the unusual form of the latter disease in which the synovial membrane is thickened and there is considerable effusion that any difficulty is likely to arise.

**Treatment.**—Little can be done to cure, but much to relieve and retard. Rest and strapping the joint in iodine or stimulating plasters will afford relief; and, in many instances, the administration of the iodide of potassium will lessen the nocturnal pain. Smith recommends an electuary composed of guaiacum, sulphur, the bitartrate and carbonate of potash, and ginger, with a small quantity of rhubarb; and I have certainly seen benefit result from the administration of this remedy in some cases. Ammoniacum and cod-liver oil

are both extremely useful in some cases. When the disease is once fairly established, and has assumed a very chronic character, it will be found of great importance to give the affected joint as much rest as possible, without confining the patient to the couch or house. This is best effected by his wearing a proper supporting apparatus. When the hip or knee is the seat of the disease, the apparatus should consist of a firm leather pelvic band having a steel rod extending down the outside of the limb, hinged angularly opposite the hip, knee, and ankle, and fixed into a socket in the sole of the boot, and properly adjusted by means of straps and moulded leather to the thigh and leg. By the use of this apparatus the weight of the limb is taken off, and all rotatory movement of the hip is prevented, to-and-fro motion being allowed. Thomas's hip- or knee-splint will sometimes be found useful.

Mineral waters and baths are often beneficial in the treatment of rheumatoid arthritis; those of Wildbad and Franzenbad in Germany, of Aix-les-Bains in Savoy, Barèges and the other Pyrenean sulphurous waters in France, and Buxton and Bath in this country are among the most useful. That warm douching and bathing may give great relief is undoubted. But that they can cure an organic joint disease of the nature of rheumatoid arthritis is scarcely within the bounds of probability.

#### **Chronic Rheumatoid Arthritis of the Hip.**—

This form of the disease commences with pain in and about the joint, increased at night, and especially in damp or cold weather, presenting in this respect the ordinary characters of a rheumatic affection. As the disease advances, the pain, which is continuous, is much increased by standing or walking, and the movements of the joint become gradually more and more impaired. The patient experiences the greatest difficulty in bending the body forwards from the hips; he consequently is unable to stoop, or to sit in the ordinary position, being obliged to keep the limb straightened in nearly a direct line with the trunk. The difficulty in walking, in standing erect, in stooping and in sitting increases. The trochanter will be felt to be thickened. The limb becomes gradually shortened to the extent of about an inch or more, owing to changes that take place in the head and neck of the bone. The pelvis also assumes an oblique direction, and hence the apparent shortening becomes considerably greater. The knee and foot may either be inverted or everted, and the heel is raised. The hip also becomes flattened posteriorly, the gluteal muscles waste so that the fold of the nates diminishes and sinks to a lower level, but the trochanter projects, and on examination seems larger and thicker than natural (Fig. 543). On rotating the limb, the movements of the bone are extremely limited, and crackling, grating, osseous crepitation will often be felt around the joint. As Smith remarks, the lumbar vertebræ acquire great mobility. The thigh on the affected side is wasted, but the calf retains its natural size and firmness.

**Pathological Changes.**—On examination after death, the changes already

Fig. 543. — Chronic Rheumatoid Arthritis of Right Hip-joint.

described as characteristic of rheumatoid arthritis will be found. The round ligament is destroyed, and the head of the bone is remarkably altered in shape, being flattened, greatly increased in size, or placed more or less at a right angle with the shaft, sometimes elongated, and always very irregular and tuberos. The neck is more or less absorbed, and in some cases appears as if it had undergone fracture. The acetabulum generally becomes enlarged, sometimes of a more or less circular and flattened shape; but in other cases projecting and narrowed at its rim, embracing tightly the head of the femur (Fig. 544). Both it and the upper part of the femur become porous, and perforated with numerous small foramina. Masses of bone are commonly thrown out about the base of the trochanter, but more particularly along the intertrochanteric line, within the capsule of the joint, and not unfrequently in the soft tissue around it. In many cases the apparent increase in the size of the head of the bone is dependent on the deposition of these masses of osseous tissue upon it, rather than on any expansion of the upper articular end of the thigh-bone. These masses of bone constitute one of the most important characters

Fig. 544.—Section of Hip-joint affected by Chronic Rheumatoid Arthritis.

of the disease. The muscles and soft structures in the vicinity of the joint are necessarily wasted from disuse.

**Diagnosis.**—It occasionally happens that an individual labouring under this affection meeting with a fall or contusion on the hip, presents signs of *fracture of the neck of the thigh-bone*, such as shortening, eversion, with some crepitation perhaps, and inability to move the limb. The diagnosis may in general be made by attention to the history of the case, and by eliciting the fact that the symptoms have existed to some degree before the accident, although the pain and immobility may have been increased by it.

**Chronic Rheumatoid Arthritis of the Lower Jaw.**—Chronic rheumatoid arthritis has also been described by Smith as occasionally affecting the temporo-maxillary articulation in individuals of rather advanced age. This disease is often symmetrical, and gives rise to an enlargement of the condyle of the jaw, which can be felt under the zygoma, attended with much pain in opening the mouth, a sensation of cracking or grating in the joint, and some enlargement of the lymphatic glands in the neck. The pain is generally increased at night, and influenced by the state of the weather. The face

becomes distorted, the affected side of the jaw projecting and being pushed towards the opposite side ; but when both joints are affected, the chin projects, the entire jaw being drawn forwards. This distortion is chiefly owing to the destruction of the articular eminence : for, when this takes place, the external pterygoid muscle draws the jaw forwards and to the opposite side ; but when both articulations are equally affected, these muscles displace it directly forwards : the glenoid cavity becomes enlarged, the fibro-cartilage disappears, and the condyle is sometimes greatly thickened and flattened, and always rough, being devoid of cartilage. In such cases there is little to be done by medicines ; but the treatment must be conducted on the same principles as in the same affection attacking the hip.

**Chronic Rheumatoid Arthritis of the Shoulder.**—When it affects the shoulder, chronic rheumatoid arthritis gives rise to a considerable enlargement of the head of the humerus, wasting and rigidity of the deltoid, and inability to move the elbow upwards, except by the rotation of the scapula on the trunk. In fact the shoulder being fixed, all movements are effected through the medium of the scapula, which becomes more mobile than natural. The articulation is the seat of much pain, lancinating at times, but generally gnawing and intermittent, and greatly increased in cold and wet weather. The whole of the arm becomes wasted, and weakened in power. In two instances I have seen this disease in otherwise robust and healthy men, between twenty and thirty years of age, coming on without any apparent cause. In both cases the rigidity persisted, though the pain was relieved by the use of the iodides and by counter-irritation.

#### DISEASES OF JOINTS OF CEREBRAL OR SPINAL ORIGIN.

The so-called *arthropathies* occurring as the result of diseases of the central nervous system may be divided, according to Charcot, into two classes :—

1. **Arthropathy of Paralysed Limbs.**—Acute or subacute inflammation with considerable swelling from effusion into the joint, and more or less severe pain, is occasionally observed in the articulations of limbs paralysed from acute or subacute inflammation of the spinal cord. Mitchell has observed it in paraplegia from spinal caries ; Viguès, Joffroy, and Gull as the result of paralysis from traumatic lesion of the cord ; Scott, Alison, and others have also met with a similar affection of the joints in limbs paralysed from circumscribed cerebral softening, or intracerebral hæmorrhage. It comes on at the same time as the contraction of the muscles commences, usually fifteen days to a month after the paralysis has set in. It has no tendency to end in supuration.

2. **Arthropathy of Ataxic Patients, or Charcot's Disease.**—This condition was first described by Charcot. It was exhaustively investigated by a Committee of the Clinical Society of London, by whom a valuable report was published in 1887. The disease occurs in patients suffering from locomotor ataxy, setting in without apparent cause at various stages of the malady, either before or after the appearance of the ataxic symptoms in the limbs. Thus in 47 cases collected by the Committee above mentioned, in 10 the joint lesion was situated in the upper extremity, and in only one of these were there any signs of want of co-ordination in the movements of the limb. In 37 the joints of the lower limb were affected, and in 20 of these there was

no ataxy at the time when the disease appeared. The onset of the joint affection may be sudden or gradual. The sudden invasion is most characteristic, and occurs in more than two-thirds of the cases. It commences with a general and often enormous swelling of the limb, commonly without pain or fever. After a few days the general swelling disappears, but the joint remains distended with fluid. Sometimes the bursæ in the neighbourhood of the articulation are also distended. The fluid, if drawn off by the aspirator, quickly re-accumulates. It is perfectly transparent, and of a pale lemon colour. At the end of some weeks or months the swelling subsides, and the joint may return in exceptional cases nearly to its normal condition. In the more typical cases, however, crackling appears on movement within a few weeks of the commencement of the attack, the ligaments become relaxed as the effusion is absorbed, and the osseous surfaces are altered in form by rapid erosion. In this stage there is coarse rough grating in flexing or extending the joint, but these movements

are unaccompanied by pain. Owing to the alteration in the bony surfaces and the relaxation of the ligaments, abnormal lateral movements, or a capability of over-extension, may be met with, giving rise to great unsteadiness in walking if the lower limb is affected. Dislocation of the diseased joint may occur, especially in the hip or shoulder. This may take place early as a consequence of extreme distension of the capsule during the stage of effusion, or at a later period as a result of the wearing away of the bones. The cases in which the disease sets in gradually more closely resemble chronic rheumatoid arthritis in their course, being characterized by gradual enlargement with alteration in

Fig. 545.—Charcot's Disease of both Elbows.

form of the ends of the bones accompanied by painless grating on movement. The accompanying figure (Fig. 545) well illustrates the appearances both in the early and the late stages of Charcot's disease. The right elbow was attacked in 1885, after the patient, a man aged about 40, had suffered from symptoms of locomotor ataxy for two years. The joint became rapidly and painlessly distended with fluid. As this subsided, it was found that the bones of the forearm were partially dislocated inwards, and there was free lateral mobility in the joint. In 1887 the joint presented the appearance shown in the figure. It was much deformed by bony outgrowths, the dislocation remained as before, but the lateral mobility had disappeared. Flexion and extension were painless but accompanied by coarse grating, and were slightly limited in extent. At the time the photograph was taken in 1887, the patient was suffering from an acute attack in the left elbow. The whole arm was enormously swollen, and in parts red and brawny, pitting under very firm pressure. There was a sensation of tightness of the skin, but no actual pain

even when the joint was moved. There was coarse grating on moving the joint. The capsule was tensely distended with fluid. Two months after, the swelling was gradually subsiding. In 1885 the patient suffered from a temporary attack of neuritis of the right musculo-spiral nerve with paralysis of the extensors of the wrist and fingers. An analysis of the 66 cases collected by the Committee of the Clinical Society shows that in 41 a single joint was affected, in 19 two joints, and in only 6 were more than two attacked. In the 66 cases 100 joints were affected in the following order of frequency: knees, 45; hips, 24; shoulders, 13; elbows, 7; tarsus, 5; metatarso-phalangeal joints, 4; wrist, 1; phalangeal joints, 1.

The *pathological appearances* found after death are similar to and in many cases identical with those already described as being met with in rheumatoid arthritis (p. 354). The chief differences are, first, that the wearing away of the surfaces is often very extensive, and that the formation of ossifying cartilaginous outgrowths round the joint is very limited, or even wanting; and secondly, that true dislocations are common from relaxation of the ligaments, whereas in rheumatoid arthritis they are rare, and when present are due, not to relaxation of the ligaments, but to pressure of the bony outgrowths. It has been suggested that Charcot's disease is merely rheumatoid arthritis occurring in a patient suffering from locomotor ataxy, and that the wearing away of the bones is aggravated by the inco-ordinate movements of the limbs and the want of sensation in the joint. There seems, however, little reason to regard this as the true explanation of the disease, for it usually sets in before marked inco-ordination is present. It is further distinguished from arthritis deformans by its most commonly affecting a single joint, by its sudden invasion, by the abundant effusion commonly met with in the early stages, by the occasional retrogression of the disease, and by the abnormal lateral mobility, in all which points it is the exact reverse of rheumatoid arthritis. The Committee of the Clinical Society after careful inquiry failed to find any case presenting the characteristic features of Charcot's disease in which the symptoms of *tabes dorsalis* were completely wanting. For the description of this disease I must refer the reader to works on medicine. It must suffice here to mention that the chief symptoms to be looked for are loss of knee-jerk, loss of sexual power, occasional incontinence of urine, loss of reaction of the pupil to light while it still accommodates itself for near vision, want of co-ordination in the muscles of the limbs, inability to walk steadily with the eyes shut, lightning pains in the limbs and joints, occasional delayed or otherwise modified sensation in the limbs, and a history of the so-called "gastric crises."

The *Treatment* of the disease is very unsatisfactory. Nothing can be done to cure, but the limb may sometimes be made more useful, and the destructive processes delayed by properly fitted supports or splints. Aspiration is occasionally useful to relieve the distension of the joints, but its effect is merely temporary. Pressure is also ineffectual in preventing the early effusion into the joint.

#### ANKYLOSIS OR STIFF JOINT.

ANKYLOSIS is invariably the result of partial or total destruction of a joint by inflammation, and is one of the modes by which nature effects its repair. It consists in the more or less complete consolidation of the parts around and

within the articulation. It is of two kinds: the Incomplete, or Fibrous; and the Complete or Osseous.

In the **Incomplete** or **Fibrous Ankylosis**, the stiffness of the joint may be dependent on four distinct pathological conditions which may be more or less associated:—1, on thickening and induration of its fibrous capsule; 2, on the formation of fibroid bands as the result of inflammation within the joint; 3, in consequence of the cartilages and synovial membrane being in part or wholly removed, and their place being supplied by a fibroid tissue, by which the articular ends are tied together; 4, on shortening of the ligaments on the side of flexion of the joint. The stiffness of the joint may be materially increased by the shortened and contracted state of the muscles around the joint, but this is secondary to, and not an essential part of, the ankylosis. Fibrous ankylosis commonly results from rheumatic or gonorrhoeal arthritis, and is the most favourable result that can be hoped for in many cases of tuberculous disease. It sometimes arises simply from disuse; the ligaments being shortened, and the limb becoming stiffened in the position in which it has been too long retained.

**Complete or Osseous Ankylosis** is of two kinds. In one, all the soft parts within the joint are destroyed, and the osseous surfaces have coalesced, or are fused together by direct bony union; this is most commonly seen in the hip (Fig. 546), knee, and elbow. In the other kind the bones are united partly by fibrous tissue, and partly by arches or bridges of osseous tissue thrown out externally to the articulation, and stretching across from one side to the other. In some very rare cases these bony masses may be formed partly by ossification of the ligaments. There is a specimen illustrating this in the

Fig. 546.—Osseous Ankylosis of Hip.

Museum of University College. In it the knee is completely ankylosed in an over-extended position, and the ossified ligamentum patellæ is clearly to be recognized. Ankylosis of the vertebrae occasionally occurs in this way giving rise to the condition known as "*spondylitis deformans*." It is supposed to be a chronic rheumatic affection, probably in some instances gonorrhoeal, and is characterized by ossification of the ligaments connecting the vertebrae, especially the anterior common ligament and the capsules of the joints between the articular processes. The true or osseous ankylosis does not often occur as a consequence of tuberculous arthritis, but is usually the result of pyæmic or traumatic inflammation in persons of a healthy constitution. It not unfrequently happens, in old-standing cases of diseased joint, that more or less complete ankylosis is taking place at one part of the articulation, whilst caries, or necrosis of the bones, is going on at others. It is usually easy to make the *Diagnosis* between fibrous and osseous ankylosis; the joint being movable, though perhaps only to a very slight degree, in the former, whilst it is rigidly and immovably fixed in the latter. In fibrous ankylosis, moreover,

any attempt to move the joint by force is usually accompanied by severe pain with involuntary contraction of the neighbouring muscles, whilst in osseous ankylosis such attempts, unless extremely forcible, are painless. Cases not unfrequently occur in which the rigidity of the structures, muscular and capsular, outside the joint, is so great in the fibrous, and the mobility of the neighbouring bones and joints so free in the osseous, that it becomes very difficult to decide to what degree the joint is stiffened. Here the diagnosis may be made by putting the patient under an anæsthetic, when if the ankylosis be fibrous, the joint will be found to yield.

**Treatment.**—The treatment of ankylosis is, in the first instance, of a precautionary nature: that is to say, when the Surgeon finds that the establishment of ankylosis is, as it were, the natural means of cure adopted by Nature in a deeply diseased joint, his efforts should be directed to taking care that the joint shall become fixed in such a position as will leave the most useful limb to the patient. Thus, if it be the hip or knee, the ankylosed joint should be in a straight position; if it be the elbow, it should be placed at a right angle, and the hand in the mid-state between pronation and supination.

When once ankylosis has occurred, the treatment to be adopted will depend partly on the degree of stiffness, whether it be fibrous or osseous; and partly on the object to be attained, whether this be merely the restoration of mobility in a part ankylosed in a good position, or the remedying of the deformity occasioned by faulty ankylosis.

1. In attempting to restore the mobility of a joint ankylosed in a good position, as of a straight but stiff knee, the Surgeon may usually succeed, if the ankylosis be only fibrous, (when some degree of movement will always be perceptible in the part) by the employment of passive motion, frictions, and douches, more particularly with warm salt water or the sulphurous mineral springs. In the more obstinate cases, and where the immobility appears to depend, in some degree at least, on fibrous bands stretching across the joint, an attempt might be made to rupture these by forced movements under an anæsthetic.

2. When fibrous ankylosis has taken place in a faulty position—if, for instance, the knee be bent, or the elbow straight—the first thing to be done is to place the limb in such a position that it will be useful. This may most readily be done by putting the patient under the influence of chloroform, and then forcibly flexing or extending the limb as the case may require, when with loud snaps and cracks it will usually come into proper position. Should any of the tendons or bands of fascia near the joint appear to be particularly tense, they may be divided subcutaneously some days before the extension is attempted, or else, if it have been carried as far as the rigid state of the tendons will permit, tenotomy may then be practised, and, an interval of a few days having been allowed to elapse, extension may be completed. The muscular contraction will, however, in many cases, yield to gradual extension by means of weights, and thus render tenotomy unnecessary. Sayre states that when the contracted tendon is stretched to the utmost, if a reflex contraction of the muscle can be felt by the finger pressed upon it, it is better to divide it. If no reflex contraction ensue, stretching alone is sufficient. The inflammation that follows this forcible extension or flexion of the limb, is usually but very trivial; an evaporating lotion and rest will speedily subdue it. Indeed, it is surprising what an amount of violence may be inflicted on an

ankylosed joint without any bad consequences ensuing. After the limb has been restored to its proper position, passive motion and frictions may tend to increase its mobility.

3. When osseous ankylosis has taken place, and the position of the limb is a good one, it will generally be wiser for the Surgeon not to interfere; except in the case of the elbow-joint, which, in these circumstances, may be excised with advantage, so as to substitute a movable for an immovable articulation. If the position be faulty, the osseous union may be sawn, drilled, or chiselled, and broken through subcutaneously; or a wedge-shaped piece of the bones may be taken out, and the position of the limb thus rectified.

4. Amputation may be required in cases of faulty ankylosis with so much atrophy of the limb as to render it useless, or in cases in which there is necrosed or carious bone co-existing with ankylosis and rigid atrophy of the muscles of the limb.

#### LOOSE CARTILAGES IN JOINTS.

It sometimes happens that the synovial membrane of a joint assumes a **Warty Condition**, as the result of chronic disease of the articulation, especially in rheumatoid arthritis. This warty state of the membrane arises from hypertrophy of the fringes, chiefly in the neighbourhood of the margin of the cartilages. These may become pedunculated, and pendent into its interior. For this condition, which gives rise to occasional uneasiness and puffiness about the joint, with a crackling or creaking sensation when it is moved, but little can be done beyond the application of a flannel bandage or an elastic knee-cap.

**Loose Bodies** may be of three kinds. 1. The so-called *melon-seed bodies*. These are usually numerous, sometimes fifty or more in number, white or brownish in colour, and closely resemble the seeds of a melon in form. They are composed most commonly of dense fibroid tissue, and are believed to be due, in many cases at least, to the pedunculated, warty, or villous growths just described as being formed from hypertrophy of the synovial fringes, becoming separated from their attachments by the movements of the joint. In other cases it is possible they may be formed from altered clot, as blood-crystals have been recognized in them. Lastly, König first pointed out that in many cases they are formed from a fibrinous exudation from the synovial membrane due to very chronic tuberculous disease. In some cases he demonstrated the presence of tubercle in the synovial membrane. (See Tuberculous Dropsy, p. 346.) Melon-seed bodies are more common in the sheaths of tendons and in synovial bursæ than in joints, and in these situations also it has been shown by Nicluse, Poulet, and Vaillard, that they are due to chronic tuberculosis of the membrane.

2. *Fragments of true cartilage*. These may be developed in two ways: first, from the formation of cartilage in the hypertrophied fringes of a warty synovial membrane. In the normal condition a cartilage cell is present in many of the secondary papillæ of the fringes, and it is easy to understand how this can form the starting-point of a cartilaginous growth. In other cases, Billroth believes that they are ossifying cartilaginous growths formed in the fibrous layer of the synovial membrane in rheumatoid arthritis (p. 254), which have subsequently become loose by the wearing away of the superficial layers of the membrane. This mode of origin is somewhat doubtful. These

cartilages are usually flattened, with a lobulated irregular border, and frequently contain true bone in their central parts; sometimes they may be partly calcified, but contain no true osseous tissue. They may attain a size of more than one inch in their greatest diameter. They are usually single, but occasionally four or five may be found in the same joint. There is strong reason to believe that these cartilaginous bodies may increase in size after becoming loose in the joint.

3. Numerous cases have been recorded in which the loose body was believed to be a piece of one of the articular cartilages broken off by mechanical violence. This variety presents the ordinary appearance of articular cartilage, and may usually be recognised by having one smooth surface, while the opposite side has small gritty fragments of bone attached to it, which have been torn from the cancellous tissue beneath. Humphry of Cambridge, whilst admitting the existence of this variety, points out that a loose cartilage formed in the synovial membrane, and containing a bony nucleus, may gradually come to resemble closely a piece of articular cartilage by the wearing away of its surface on one side and exposure of the bone within. The loose cartilage may gradually wear for itself a bed in one of the articular surfaces and thus still further resemble a portion removed by an injury.

Loose cartilages of all kinds are most commonly met with in the knee, but not uncommonly occur in the elbow or the joint of the lower jaw, and occasionally in the shoulder.

**Symptoms.**—The severity of the symptoms will to a great extent depend upon the mobility of the loose cartilage, and its consequent greater or less liability to be nipped between the opposite articular surfaces in the movements of the joint. When these bodies are tolerably firmly attached to the synovial membrane, they may merely cause weakness of the joint, with occasional synovial effusion. When loose they usually give rise to a very distinct train of symptoms. The most marked of these is the very severe pain which occurs in particular movements of the limb. This comes on suddenly, and is often so intense as to cause faintness or sickness. It is usually followed by a degree of synovial inflammation, and by relaxation of the ligaments. These attacks of sudden pain come on at varying intervals, as the result of movements of the joint: they commonly happen in the knee whilst the patient is walking. It is difficult to say to what this severe pain is due. Richet thinks it may be owing to the synovial membrane being pinched between the foreign body and one of the articular surfaces. I think that it is most probably due to the foreign body being drawn in between the opposite surfaces of the joint, when these are separated anteriorly in the act of flexion of the knee, and then, when the limb is extended, acting as a wedge between these, tending to keep them separate and interfering with the complete straightening of the limb. In consequence of this wedge-like action of the loose cartilage the ligaments are violently stretched, and the sickening pain consequent on this is experienced, followed, as happens in a violent sprain, by rapid synovial effusion. Ligaments may be cut without much suffering, but, on account of the nature of the nerve endings in them, they cannot be stretched, either by accident or disease, without the most severe pain. In some cases the loose cartilage can be felt under the capsule, by carrying the finger over the joint, slipping back when pressure is exercised upon it, and often possessing great mobility, gliding from one side of the joint to the other, so as to be extremely difficult to fix.

**Diagnosis.**—The only condition likely to be confounded with a loose body is the displacement of one of the interarticular fibro-cartilages of the knee. The distinction can usually be made by observing that immediately after the sudden attack of pain the knee can be completely extended when it is due to the presence of a loose body, as this rarely if ever remains jammed between the articular surfaces; while a displaced fibro-cartilage usually remains out of position until replaced by manipulation or movement of the joint, and until this is effected complete extension is impossible (see Vol. I., p. 708).

**Treatment.**—The palliative treatment consists in supporting the joint with an elastic bandage or knee-cap, so as to limit its movements, and thus prevent the liability to recurrence of the attacks of pain; and in this way the fixation and ultimate absorption of the cartilage may sometimes be obtained. This I have several times seen to occur in patients who either refused to be operated on, or in whom an operation was not thought advisable. Any inflammation that has been excited requires to be subdued by proper local treatment. In all operations for the removal of loose cartilages antiseptic precautions of the most rigorous character should be adopted. By their aid joints may be opened and explored, and foreign bodies extracted with a freedom and safety otherwise unattainable.

If the cartilage occasion frequent suffering, so as to interfere seriously with the utility of the limb, and if it appear to be of large size, and to be loose and single, means may be taken for its extraction. But it must be borne in mind that any operation for its removal by which the joint is opened, becomes a source of danger to limb and even to life unless efficient means are adopted for the prevention of septic arthritis. Although by the proper use of antiseptics this danger may be averted with almost absolute certainty, it is wiser not to undertake the operation without warning the patient of the possible consequences that may follow. No operation should be undertaken so long as the joint is in an irritated state, as the result of a recent attack of pain and inflammation; this must first be subdued, and then the operation may be proceeded with; nor should it be done if the patient's health be broken.

The extraction of the foreign body has been performed in two ways: by direct incision into the joint, and by subcutaneous section. In the operation by direct incision the patient must in the first instance make those movements by which he usually gets the cartilage fixed in the joint. As soon as the Surgeon feels it (as this operation is commonly required in the knee), he pushes it to one side of the patella, where he fixes it firmly with his forefinger and thumb, and an anæsthetic may then be administered. The incision is then made down to the capsule of the joint over the loose body. All bleeding should then be arrested, after which the incision may be carried through the capsule and synovial membrane and the loose body may be squeezed out or extracted by means of a sharp hook. Unless the wound be large it is wiser not to close it by sutures; an antiseptic dressing may be applied and the limb rigidly fixed on a proper splint. In cases in which the body is very large, or in which much manipulation of the joint has been necessary so that some synovial effusion may be expected, it may be advisable to insert a drainage-tube for a few days, but, as a rule, this is not necessary. The wound should be irrigated during the operation, and great care taken to prevent the entrance of air into the articular cavity. Before the introduction of antiseptic surgery the foreign body was sometimes removed through a valvular wound made by

drawing the skin on one side after the first incision before opening the capsule. Anything like a valved opening should be carefully avoided when antiseptics are used, as it interferes with drainage. Formerly the operation was not uncommonly followed by septic arthritis, ending in ankylosis of the joint, or the death of the patient, and sometimes necessitating amputation of the limb. In the present day it is rarely followed by synovial inflammation even of the slightest kind.

It was proposed by Chassaignac, in order to obviate the dangers of a direct opening into the joint, to remove the loose cartilage by subcutaneous section. In operating by this method on the knee, the cartilage should be fixed below and to one side of the patella, between it and the head of the tibia; a long narrow tenotome is then introduced obliquely under the skin from a distance of about two inches below the loose cartilage; the capsule of the joint is freely divided, and a space made in the subcutaneous areolar tissue by a slight sweep of the blade; the loose cartilage is next pressed into the cavity thus made to receive it, and slid along the areolar tissue for about two inches. It is fixed *in situ* with a firm pad and adhesive plaster; the foot and leg are bandaged up to the edge of the cartilage, and the limb is placed on a splint. If no inflammatory symptoms ensue, the cartilage is excised about a week after the operation; or it may be left to be absorbed. By the adoption of the subcutaneous method there will be very little danger of inducing undue inflammation in the joint, the entrance of air being prevented; it is this, and not the mere section of the capsule and synovial membrane, which constitutes the chief risk. Should there be more than one loose cartilage, the operation must be repeated, but not until any inflammation induced by the former one has been subdued. In this way I have successfully removed in succession five loose cartilages from one knee.

#### CYSTS IN CONNEXION WITH JOINTS.

Morrant Baker has called especial attention to the occurrence of cysts in the neighbourhood of diseased joints, appearing superficially at such a distance from the articulation that their connexion with it may not at first be apparent. These cysts are of various kinds. It has already been pointed out that in hydrarthrosis pouch-like projections may protrude from the synovial membrane owing to the pressure of the fluid effused into the joint. This may occur in tuberculous dropsy (p. 346), or in Charcot's disease. The fluid thus escaping from the joint may, while still contained in a thin membranous sac, extend to a considerable distance from it. Thus, from the knee it may reach to the middle of the calf, or from the shoulder along the long tendon of the biceps to the middle of the arm. The communication with the joint may be so small that pressure will not force the fluid into the articular cavity. A chronic abscess from a diseased joint may follow the same course, and become superficial at a point far removed from its point of origin. In other cases cysts may be formed by distension of bursæ or synovial sheaths in the immediate neighbourhood of a diseased joint either communicating or not with its cavity. Thus the bursa under the inner head of the gastrocnemius in disease of the knee or that under the deltoid in the shoulder, or under the psoas and iliacus in the hip, may become distended with fluid. The so-called "compound ganglion of the wrist" is often associated with chronic tuberculous

disease of the radio-carpal articulation. In this form melon-seed bodies are often present.

The incautious puncture of these cysts without efficient antiseptic precautions, under the impression that they had no connexion with the neighbouring joint, has in several recorded cases been followed by septic arthritis and destruction of the articulation. Mere puncture or aspiration cannot from the nature of the case be productive of much benefit. These cysts may, however, safely be incised and drained if proper antiseptic precautions are taken. In some cases, in spite of treatment by incision or otherwise, the tuberculous nature of the affection becomes manifest after a time by progressive disease in the articulation. In two cases of compound ganglion of the wrist in University College Hospital, incision and drainage apparently cured the patients, but some months afterwards tuberculous disease developed in the radio-carpal and carpal articulations, necessitating excision of the wrist in both cases.

#### NEURALGIA OF JOINTS.

Pain of a severe character is often experienced in or around a joint, closely simulating, but not dependent upon, inflammation or other structural disease. This pain, which is purely neuralgic, may have its origin either in some local irritation of a nerve leading to the sensitive part, or in constitutional disorder of a hysterical character. **Neuralgia of the Joints**, to which attention was directed principally by Benjamin Brodie, occurs chiefly in young women who are either the subjects of hysteria, or are of a highly nervous temperament. This is not, however, invariably the case, for a similar condition may occur in men who exhibit none of the emotional symptoms of hysteria.

**Symptoms.**—It is generally found that the hip, knee, ankle, or shoulder is the joint affected—the hip and the knee more especially. The neuralgia is usually localized in a particular joint by some slight injury that the part has sustained. But it is important to observe that in these cases the pain often does not develop for some days, or even weeks, after the injury that is the alleged cause of it. Severe pain in the joint is complained of; and the limb is rendered comparatively useless, often with a good deal of distortion or contraction. On examination, it will be found that the pain, which is commonly very severe, is superficial and cutaneous, not existing in the interior of the articulation, nor increased by pressure of the articular surfaces against one another; and that it is not strictly confined to the joint, but radiates for some distance around it. This pain is often intermittent in its character, and is frequently associated with neuralgia elsewhere, as in the spine; and not unfrequently with uterine irritation or disease. The patient sometimes acquires the trick of producing loud snappings of some muscle or tendon which are distinctly audible all over the room whenever she walks or moves. At the same time, it will be observed that all the signs that ought to accompany a severe attack of inflammation in a joint, such as would be attended by a corresponding amount of pain, are absent: there being no painful startings of the limb at night, no heat, redness or swelling, no elevation of temperature; and the suffering being increased by causes, such as mental and emotional disturbance, that do not influence organic disease. Attention to these various circumstances will usually enable the Surgeon to recognise the

nature of the attack without much difficulty; the only cases in which he will really experience any being those in which the tissues around the joint have been thickened, indurated, and altered in their characters by the application of counter-irritants; or by some slight articular disease having at some time existed, but having been cured.

**Causes.**—The neuralgia is often referable to the irritation of some particular nerve, either at its origin or in its course. This is particularly the case with neuralgia of the hip or knee, which will often be found to be dependent on irritation of the obturator nerve, owing to intrapelvic disease. In one case of secondary abdominal cancer under my care, the patient was seized with the most intense pain in the right hip and knee, so as to lead to the suspicion that these joints were diseased. On examination after death, it was found that the pain resulted from the implication of the obturator nerve in a mass of intrapelvic growth, the joints themselves being perfectly sound.

**Treatment.**—The treatment must be constitutional, directed especially to re-establish a healthy condition of the uterine organs. If there be amenorrhœa and anæmia, aloëtics and the preparations of iron must be given; if ovarian or uterine irritation or congestion exist, this must be removed by proper local means, and the general health attended to. Nervine antispasmodics and tonics, such as valerian and bark, or assafœtida and quinine in full doses should be administered. The most efficient treatment that can be directed to the affected joint is the application of cold douches and the employment of the continuous electric current, which will cure cases in which all other means have failed; the application of atropine and aconite may be of service in allaying the pain when especially severe. If contraction or other distortion of the limb exist, the patient should be put under an anæsthetic, and extension or rectification of the faulty position then made, care being taken to keep the limb on splints in a proper position for some time after the operation. Indeed, in neurotic or hysterical joint affections, it is often of much use to do something positive or objective in the way of treatment, so as to give the patient an excuse to get well. It is thus that free manipulation or slight "wrenching" of the joint under anæsthetics is often beneficial. In other cases the good effects following this treatment may be explained by the stretching and restoration of the normal position of muscles which had been allowed to become contracted and displaced by long continued fixity or faulty position of the joint.

## EXCISION OF JOINTS.

It will be convenient to consider here the history of the excision of joints and the general indications for the performance of the operation, leaving for subsequent consideration the operations on the individual joints.

**History.**—The operation of resection of the articular ends of bones dates from the very earliest periods of Surgery of which we have any record. Hippocrates (in his Chapter on Injuries of Joints) speaks of resections of bones at the joints, whether of the foot, the hand, the leg, the ankle, the forearm or the wrist, as being for the most part unattended with danger, except from syncope or consecutive fever. Celsus, in speaking of compound dislocations, says, if the bare bone project it will always be an obstacle to reduction; that which

protrudes should therefore be cut off. Paulus Aegineta says that, if a bone project, as after a transverse fracture, it must be cut off. Thus it is clear that it was the practice of the ancients in compound dislocations, and in compound fractures, to resect the protruding bones. But that the practice of resection in cases of disease also was not unknown to them, is evident from a passage on fistula in the works of Paulus Aegineta, who directs that, if the fistula terminate in a bone, and if that be not diseased, it should only be scraped; but if it be carious, the whole diseased portion should be cut out with chisels, and, if necessary, it may have a hole bored in it with a trephine; and a little further on he says, "the extremity of a bone near a joint, if diseased, is to be sawn off; and often, if the whole of a bone, such as the ulna, radius, tibia, or the like, be diseased, it is to be taken out entire." He makes exceptions in the case of the bones of the spine and pelvis, and the head of the femur, which he says, should not be operated on for fear of the neighbouring arteries.

The practice of resection, however, fell into disuse, and seems to have been completely forgotten until the middle of the last century, when occasional notices of its adoption appear in Surgical essays. It was first employed in cases of compound fractures and dislocations of joints. In military practice, the Surgeon, in two or three instances, picked out and cut away fragments of the bones forming the wrist, elbow, shoulder, and ankle joints when shattered by gunshot. This early revival of resection involved no principle of treatment; imperfect operations being had recourse to on the field of battle simply as a matter of convenience in particular cases.

The first resection practised for injury in which the articular ends in compound dislocation were deliberately and successfully removed, appears to have occurred to Cooper of Bungay, before, or at latest about, the middle of the last century. The precise date of this case is unknown; but Gooch writing in 1758, says that it occurred "many years ago"; that the ends of both tibia and fibula were sawn off in a compound luxation of the ankle; that the limb was preserved, and was so useful that the patient was able to walk and earn his livelihood.

In or about the year 1758, Wainman of Shripton sawed off the lower end of the humerus in a case of compound dislocation of the elbow-joint with perfect success, the patient recovering with an arm as movable "as if nothing had ever been amiss." Wainman's example was shortly afterwards followed by Tyre of Gloucester, who in a similar case removed two and a half inches of the lower end of the humerus. From this period, the operation of excision of the articular ends of bones in cases of compound dislocations and fractures into joints became an established practice, and was extensively adopted by Percy in France, who, in 1794, exhibited to Sabatier nine soldiers in whom he had successfully excised the head of the humerus for gunshot injury; by Bilguer in Germany, by Hey of Leeds, and by numerous other Surgeons in this country and abroad.

In 1768, White of Manchester removed from a boy of fourteen what he believed to be the head of the humerus, with several inches of the shaft, and the patient recovered with an arm slightly shortened, but perfect in all its movements. The history of the case, however, and the drawings accompanying it, show beyond a doubt that the joint was not implicated, the case being one of acute necrosis, with separation of the upper epiphysis. White, however,

strongly advocated excision for disease of joints, and satisfied himself by experiments on the dead body that it was practicable in the hip as well as in the shoulder. Although the head of the humerus was not removed by White, it certainly was three years later by J. Bent of Newcastle, who in 1771 excised by a formal and pre-arranged operation the carious head of the humerus with complete success. His example was followed in 1778 by Orred of Chester, who also operated successfully in a similar case. About the same time, 1775, Justamond, Surgeon to the Westminster Hospital, removed, in a case of disease of the elbow-joint, the olecranon and two inches of the ulna.

In 1762, Filkin of Northwich removed the articular ends of the femur and tibia, together with the patella, in a man affected with disease of the knee-joint, the result of a fall from a horse. Filkin was led to this operation, in consequence of having experimentally practised it on a dead subject, as a substitute for amputation of the limb, to which the patient refused to submit. The patient recovered rapidly, had a useful limb on which he was able to walk long distances, and was certainly alive nearly thirty years after the operation. This remarkable case seems to have attracted little, if any, attention, and indeed was not published until 1790, after Park of Liverpool brought before the Profession his second successful case of excision of the knee-joint, which occurred in 1789. That Surgeon had performed his first operation of this kind most successfully, as regarded utility of limb, in 1781, apparently without any knowledge of the operation that had been done by Filkin.

The example thus set by the English Surgeons was speedily followed by the Moreaus in France, who, between the years 1786 and 1789, presented various memoirs to the French Academy on this subject. The operation, however, was violently opposed by the great body of Surgeons, and, with the exception of the occasional removal of the head of the humerus, fell into almost complete neglect both in this country and abroad for a period of nearly forty years, during which time the records of Surgery do not contain as many cases in which the articular ends of bones were excised for disease. It continued in this languid state until 1821, when it received a new and vigorous impulse, as far as its application to diseases of the elbow was concerned, by the publication of Syme's essay on that subject, and by the practice of Liston some years subsequently at University College Hospital.

In 1845 these operations were again prominently brought before the Profession by the performance of excision of the head of the femur by Fergusson; and although excision of the knee-joint had occasionally been practised by Syme, Crampton, Textor, Demme, Heyfelder, and others, it was not until its revival in 1850 by the same accomplished Surgeon, that it came to be extensively practised. Since that period, the operation of excision has been applied to almost every joint within reach of the Surgeon's knife.

In considering the subject of the excision of joints, we must endeavour to lay down some general rules for the performance of the operations in those cases in which alone they are admissible.

**Indications for Excision.**—The excision of an articulation may be practised for the following reasons:—

1. As a substitute for amputation in cases in which *the joint is so extensively diseased* that the patient will be worn out by the discharge or pain, unless it be removed. Here a useful limb may be secured by the sacrifice of the diseased part.
2. In some cases of articular disease in which *amputation would not be*

*justifiable*, excision may be done in order to hasten the cure, and thus save years of suffering to the patient.

3. Excision may be done in cases in which *amputation is not practicable*; as in some cases of disease of the hip-joint or of the temporo-maxillary articulation.

4. As a substitute for other and less efficient treatment, in order to *restore the utility of a limb or joint*; as in osseous ankylosis of the elbow, or in faulty ankylosis of the knee.

5. Excision may be required in *bad compound dislocations and fractures into joints*, especially in *gunshot injuries*; more particularly in those of the head of the humerus, and of the bones entering into the elbow-joint.

As a general rule excisions are required only in those cases in which the articular ends of the bones are diseased either primarily or secondarily. If only the soft structures of a joint be involved, it usually happens that, without the necessity of resection or operation of any kind, a useful limb will result—in the upper extremity, with fair mobility of the articulation; in the lower, with more or less complete ankylosis, sufficient for a fair basis of support. But when the constitution is very strumous, or the bones are primarily or extensively affected, we can scarcely expect that the limb will recover to such an extent as to become useful. In the treatment of tuberculous disease, especially in children, excision has in many joints been to a large extent replaced by arthrectomy, and the unnecessary removal of healthy structures thus avoided.

In determining the necessity of excision the circumstances of the patient must be taken into consideration. Among the upper classes who can enjoy all the advantages of good food, change of air and careful nursing, it is rarely necessary to excise a joint, and the operation should never be undertaken till prolonged efforts have been made to obtain a cure by other means. In hospital practice, on the other hand, we have to deal with patients whose circumstances make it almost impossible for them to receive the prolonged attention essential to the recovery of a chronically diseased joint, and in them excision may often with advantage be performed at an earlier period.

**Conditions of Success.**—For resection to succeed, the following conditions appear to me to be necessary:—

1. *The disease should not be too extensive*, so that its removal would entail such an amount of mutilation of the limb as to render it less useful to the patient than an artificial member would be. This is especially important in the lower extremity. If the bones be so extensively affected as to require to be shortened by several inches, a limb would be left which would be only a useless encumbrance. In the upper extremity, length and strength are of less consequence than in the lower; the preservation of the hand is the chief thing to aim at, and, if this be effected, the bones may be encroached on to a greater extent than is proper in the lower limb.

2. The disease for which resection is practised should be *allowed to become chronic* before any operation is undertaken. For this there are two reasons:—First, in the acute stage of disorganization of a joint, it is not always possible to say, however unpromising the case may appear, whether ankylosis may not result, so that as useful a limb would be left as could be obtained by resection. And, secondly, if the joint be excised whilst acute and active disease is going on, inflammation and diffuse suppuration of the medullary canal are liable to

set in—a condition very apt to be followed by pyæmia. In the only fatal instances of resection of the elbow-joint that I have witnessed, death resulted from this cause; the operation having been performed whilst the articular affection was acute.

3. *The soft parts about the joint must be in a sufficiently healthy state.* There are two morbid conditions connected with the soft parts that may interfere with the success of resection. First, they may be so thinned and permeated by sinuses, and so adherent to the bones, that an insufficient covering would be left. Or, secondly, the long-continued existence of tuberculous disease in joints and bones may give rise to great infiltration of the tissues around the articulation with chronic inflammatory products often in a state of fatty degeneration or containing tuberculous centres either caseating or softening. The tissues in this state are incapable of healthy repair. Chronic abscesses form, leaving sinuses when they discharge their contents, and the integuments become blue and doughy; and the soft parts around the seat of operation fall into a state of disorganization that prevents alike the formation of a false joint, osseous ankylosis, or the healing of the wound, and thus leads inevitably to the ultimate amputation of the limb. Even though this exudation-matter do not exist in large quantity, if the joint be peculiarly loose, owing to softening and disorganization of ligamentous and tendinous structures, excision is not very likely to succeed, especially in the ankle or knee.

4. *The state of the patient's constitution must necessarily influence the Surgeon materially in his determination whether to resect or to amputate.* If the constitution be tolerably sound, or even if the general health have given way as the simple consequence of pain and continued discharge, resection will have a fair prospect of success. In fact, when there is hectic in consequence of continued suppuration, the removal of the joint or bone that maintains it may advantageously be practised. But if the patient is suffering from septic fever in consequence of the absorption of the discharges from ill-drained cavities opening on the surface by narrow sinuses, the operation is likely to be followed by osteomyelitis and pyæmia, and is not a safe proceeding until the constitutional disturbance has been relieved by making free incisions, and providing good drainage. These incisions should be so placed as not to interfere with subsequent excision. Again, if the constitution appear to be very much broken down, the patient being anæmic, wasted or cachectic, especially if there be an evening elevation of temperature with no suppuration in the joint to account for it, excision of the larger joints, as the knee and hip, is not desirable, as it is very probable that the patient is suffering from general tuberculosis. If the patient be very highly strumous, or decidedly phthisical, there will be little prospect of his being able to bear up through the long convalescence that often follows resection. The earlier stages of pulmonary phthisis, if unaccompanied by distinct elevation of temperature, need not be a bar to the operation. In such cases I have several times had occasion to observe that the general health improved rapidly after removal of the local disease. Extensive albumenoid degeneration of the liver and other viscera is always a serious obstacle to excision, although amputation may sometimes be safely practised.

5. *The extremes of life are unfavourable to resections.* In very early childhood, these operations are seldom necessary; the natural processes usually

sufficing, with very little assistance, to eliminate diseased bone, and the disorganized joints admitting readily enough of ankylosis. If the disease be too severe for this, it will usually be found to be associated with so strumous a constitution as to interfere with healthy reparative action of any kind. Another serious objection to these operations in young children is that, should the epiphyses be removed, the development of the limb will be to a great extent arrested. At advanced periods of life, destructive joint disease is not very common, and when it does happen, it is generally in constitutions not capable of healthy repair after these operations. It is in early adult life, when the diseases most frequently occur that render resections necessary, that these operations are best borne.

**Repair after Excision.**—The mode of repair after resection of bones or joints differs according to the circumstances of the operation.

When, as very commonly happens in cases of necrosis, the periosteum, thickened, infiltrated, and loosened, can readily be detached, or, indeed, is already separated, without injury to itself, from the dead bone, reproduction of new osseous tissue to a very considerable extent may be expected. My own observations on the fibula, tibia, and ulna, and those of Ollier and Maisonneuve, prove the importance of the periosteum as an organ of repair after the extraction of a dead shaft of bone from within it. Repair in this way is, I believe, chiefly to be looked for in the shafts of the long bones; although some Surgeons, as Annandale of Edinburgh, have described the os calcis as having been reproduced after subperiosteal excision. The remarkable osteogenetic properties possessed by the periosteum have been conclusively established by the experiments of Ollier. He has shown that a bone is much more rapidly and perfectly reproduced after removal, if the periosteum be left, than if it be removed, and he states that the osteogenetic properties of this membrane are greater in the long than in the short bones. He is of opinion also that resections of joints performed by the subperiosteal method give better results, so far as the shape and formation of the new articulation are concerned, than if this membrane be sacrificed. These observations, indeed, conclusively establish the importance of making in all cases every effort to preserve the periosteum during a resection.

When a short bone, as the os calcis, has been entirely removed, with its periosteum attached, it is never regenerated, but its place is occupied by a thick, firm, fibrous cicatrix.

In some cases in which a considerable portion of the diaphysis of a long bone is taken away, repair may be imperfectly accomplished owing to sloughing of the periosteum. In a case of this kind in which two-thirds of the shaft of the humerus were lost, Macewen succeeded in obtaining complete restoration by transplantation of small fragments of bone obtained from the wedge-shaped pieces cut out of different patients for the cure of rickety curves in the tibia. The fragments measured about two-fifths of an inch in length and thickness, and the operation was performed with antiseptic precautions. This ingenious mode of treatment certainly deserves further trial.

When a joint has been excised, either osseous or ligamentous ankylosis may take place or a false joint may be formed, and the Surgeon should endeavour to secure the form of union most suitable to the case. Thus, when the knee has been excised, as a sound and firm limb is desirable, osseous ankylosis should, if possible, be brought about; whilst in the upper extremity mobility

is of more importance than strength, and we consequently aim at obtaining firm fibrous ankylosis, allowing of some mobility at the wrist, and a false joint at the elbow. In fibrous ankylosis, the opposed bony surfaces are united to each other by dense fibrous tissue. In a false joint the ends of the bones become rounded and covered by a layer of fibroid tissue almost resembling cartilage in density and smoothness, and are united by a capsule of fibrous tissue resembling normal ligaments in structure. The inner surface of this capsule is smooth and imperfectly covered by flattened cells, and thus somewhat resembles a synovial membrane, but the cavity is moistened with serous fluid such as is found in false bursæ and not true synovia. The muscles which were connected with the articular ends that have been removed form new attachments to the bones either directly or by means of the fibrous capsule of the false joint.

The question as to the arrest of the development of the bone, and consequently of the whole limb on which an operation of excision has been performed, is one of great practical moment. It is well known to physiologists that the longitudinal growth of a bone is carried on chiefly through the medium of the layer of cartilage by which the epiphysis is attached to the

Fig. 547.—Butcher's Saw.

shaft, and which does not become ossified until the bone has attained its full length. It has further been pointed out by Humphry that the two epiphyses of the long bones of the limbs do not take an equal share in this development, that which unites last taking the greater part. Thus the upper epiphysis in the humerus and tibia, the lower epiphysis in the radius and femur, are the more important in this respect. If, therefore, in an excision practised on a growing child, the whole of the epiphysis be removed, the subsequent growth of the bone will be arrested proportionately to the share that the epiphysis which is removed takes in the development of the bone. And if that epiphysis on which the length of the bone is chiefly dependent be removed,—as, for instance, the upper epiphysis of the tibia and humerus, or the lower epiphysis of the thigh-bone—the development of the limb will be very considerably interfered with. In the adult, after ossification is completed, the epiphysis loses its importance as an organ of growth; and may be removed, if necessary, without interfering with the subsequent length of the limb, except to the extent of its removal.

The **Instruments** required for resection are strong scalpels and bistouries, straight and sharp-pointed, in addition to which I have found a strong probe-pointed bistoury with a limited cutting edge, of great utility in clearing the

bones. Periosteal elevators of various forms are necessary if the operation is to be performed subperiosteally. The forceps should be of various sizes and shapes (Figs. 518 to 521), and gouges or sharp spoons will be found useful for scooping out suspicious patches on the cut osseous surfaces. For ordinary purposes, a small broad amputating saw will be found the most convenient instrument for dividing the bones; but in some cases a narrow keyhole saw, or that introduced by Butcher (Fig. 547), will answer best. The last-named instrument is especially useful when it is intended to cut the bone obliquely, or when the space is limited; for, as the blade is narrow and its angle can be changed at pleasure, any required direction can be communicated to the cut. Some Surgeons prefer, especially in resection of the knee-joint, a short and very broad-bladed saw, the blade being of breadth greater than the whole thickness of the bone to be divided. The chain-saw is now rarely used.

**Operation.**—The steps of the operation must of course vary with the different resections; but there are some general rules that may be laid down as applicable to all cases.

1. The incisions through the soft parts should be sufficiently free to expose thoroughly the bones to be removed; they should be made, as far as practicable, parallel to tendons, blood-vessels, and nerves.

2. As little of the bone as possible should be removed. The gouge or sharp spoon may be applied to any carious cavities or patches that appear upon the surface of the freshly-cut bone; and, in this way, shortening of the bone by the saw may be materially avoided.

3. In young children the epiphyses should, if possible, not be entirely removed, as it is on the growth of this portion of bone, or rather, on that of the epiphyseal cartilaginous layer adjoining the shaft, that increase in length of the bone is mainly dependent.

4. In adults in whom the bone has attained its full length, the epiphysis may be more freely removed, if necessary. But the shaft should not be encroached upon if it can possibly be avoided, and especial care should be taken not to open the medullary canal.

5. The periosteum should be carefully preserved, being stripped off the bone where it is thickened and loosened, and manipulated very gently, so that its vitality may be impaired as little as possible.

6. It is of great importance not to confound bone softened by inflammation, but otherwise healthy, or roughened by the growth of osteophytes, with that which is carious and necrosed.

7. Skin, however redundant, should never be cut away. The flaps, at first too large, soon shrink down to a proper size, and, if trimmed, are very apt to become too scanty.

8. In cases of tuberculous disease, the pulpy granulation tissue occupying the site of the synovial membrane should be removed as thoroughly as possible, partly by scraping with a sharp spoon and partly by forceps and scissors.

9. After the operation, if the skin were previously unbroken, the wound may be treated by any of the antiseptic methods already described in the chapter on Wounds, the edges being brought together as accurately as possible and proper provision made for drainage by the insertion of tubes. If sinuses exist and the discharges are not aseptic at the time of the operation, an attempt should be made thoroughly to disinfect the wound. For this

purpose the sinuses should be scraped with a sharp spoon and afterwards scrubbed with a small piece of sponge held in a pair of forceps and soaked in a solution of chloride of zinc (gr. xl. to ʒj.), perchloride of mercury (1 in 500), or tincture of iodine (ʒij. to Oij.). The whole wound should also be washed with some powerful antiseptic solution, and afterwards treated by some antiseptic method. Thorough drainage and antiseptic treatment have of late years greatly diminished the death-rate after excisions in general, and especially of the knee. After the dressing is applied, the limb must be placed on a pillow or a well-padded splint according to the joint operated on. As healing progresses, great attention must be paid to position, and passive movement must be commenced after the first week when a movable joint is desired.

10. The constitutional after-treatment should be nourishing or stimulating. As there may be a great drain on the system should profuse suppuration set in, with prolonged confinement to bed, the strength must be kept up under it by good diet. These operations are always serious; in many cases fully as much so as the amputation of a corresponding part, or even more so, owing to the large wound that is often inflicted in the more extensive division of the bones; to the necessity of making the incisions in the midst of diseased structures; and to the more prolonged character of the after-treatment.

11. Should caries or necrosis return after the operation, *secondary resection* may be required. This I have done successfully at the hip, shoulder, and elbow joints. In the elbow, in one case I performed a third resection with perfect success; the two previous operations, which had been performed by other Surgeons, having failed.

## CHAPTER XLIX.

DISEASES OF THE BONES AND JOINTS OF THE  
UPPER EXTREMITY.

In the preceding chapters we have considered the most important diseases to which the bones and joints are liable, together with the principles involved and the methods employed in their treatment. It remains to indicate the special features exhibited by these various diseases as they affect the more important individual bones and joints of the extremities, and to describe the operative procedures required for their treatment.

In the consideration of the excisions which are often required in the upper limb, it must be remembered that the whole extremity is subservient to the hand. By the excision of any one articulation the limb may be shortened, and it may be weakened; and yet, if sufficient length and strength be left to enable the individual to use his hand, an immense gain will result. Hence, provided the Surgeon can save the hand, he need not hesitate to sacrifice other portions of the limb; and the shoulder, elbow, or wrist, may be removed, and the patient left in the possession of a most useful member—shortened, it is true, and to a certain extent curtailed in its movements, but possessing all the delicate motions of the hand in full perfection.

## DISEASES OF THE CLAVICLE.

Syphilitic periostitis of the clavicle is not uncommon, and may result in the formation of a considerable fusiform node on the bone. Necrosis may follow the breaking down of a subperiosteal gumma. Tuberculous disease may occur as a subperiosteal deposit, or more rarely centrally. Tuberculous caries of the inner end of the clavicle may be associated with destruction of the sterno-clavicular joint, for which in a few cases excision has been practised. In the majority of cases caries of the clavicle can be efficiently treated by scraping, but in rare instances partial, or even complete, resection of the bone has been found necessary.

Sarcoma of the clavicle is rare. The disease is more often subperiosteal than central, and in the former case is very malignant. It most commonly affects the sternal extremity. The treatment consists in the partial or complete removal of the bone.

**Excision of the Clavicle.**—In caries or necrosis of this bone, portions of it may be gouged away or extracted without much difficulty, the bone being rarely affected through its whole thickness, and its posterior part not requiring removal; but when, in consequence of the growth of tumours, the removal of the whole or greater part of the bone is necessary, the operation is one of the most hazardous in surgery, as a glance at the anatomy of the parts lying beneath the bone, and encroached upon by the morbid growth, will indicate. It is obviously impossible to lay down definite rules for the performance of an

operation in which the circumstances must vary so greatly in each case, as in this, and for the safe conduct of which the Surgeon must be indebted mainly to his anatomical knowledge. It may be stated generally that the bone requires to be exposed by a free incision along its whole length: it is then ~~sawn across~~ or disarticulated at its acromial articulation, and carefully dissected out in a direction from without inwards, the sternal end being forcibly twisted out, and its ligamentous connexions cautiously divided, care being taken to avoid the important vessels and nerves in the lower part of the posterior triangle of the neck, and to prevent, by ligature before division, the entry of air into any vein which it may be necessary to divide. In 1828 Mott partially excised the clavicle in a man of nineteen for a central "osteosarcoma," which measured four inches in diameter. The operation was one of great difficulty; it occupied four hours in its performance, and forty ligatures were required to restrain the hæmorrhage. The subclavian vein, thoracic duct, and phrenic nerve were exposed, but the patient made a good recovery and lived to the age of seventy-three. The immediate mortality from the operation has not, indeed, been high: thus of sixteen cases of partial or complete excision for sarcoma collected by Bowreman Jessett, 12 recovered from the operation. In many of the cases rapid recurrence followed. In Jessett's case, in which the tumour was subperiosteal, small recurrences were removed and the patient was well and could use the limb freely four years after the operation. In addition to Mott's case reference may be made to three others in which the tumour was central. Of two mentioned by Butlin, one was lost sight of after the operation, and in the other recurrence took place in two months. In a third case Bland Sutton removed the outer half of the clavicle for a myeloid tumour of the acromial end; the patient was free from recurrence nearly four years later.

The sternal end of the clavicle has been excised by Davie of Bungay in a case in which dislocation backwards had resulted from deformity of the spine, and the luxated end, gradually pressing upon the œsophagus, threatened the life of the patient. The bone was cut through by means of a Hey's saw about an inch from its sternal end, and, the sterno-clavicular ligaments having been divided, the portion of bone was forcibly elevated and extracted.

#### DISEASES OF THE SCAPULA.

Caries and necrosis, resulting from tubercle or syphilis do not very commonly affect the scapula primarily. When the bone becomes the seat of these diseases, it will generally be found that the acromion and the spine are the parts affected. In such cases the progress of disease is usually very slow, and in most instances the carious bone may be effectually gouged out, or the sequestrum extracted, by laying open sinuses, and thus exposing the diseased osseous surface by irregular and informal operations. Necrosis and caries have, however, sometimes occurred to such an extent as to necessitate partial or even complete excision of the bone. In two instances the whole bone has been excised for disease of this kind following amputation at the shoulder-joint for caries of the humerus. The operators were Rigaud of Strassburg, and Fergusson. Both cases did well.

Syphilitic nodes are not very uncommon on the acromion and spine of the

scapula, and extensive necrosis of the body of the bone may follow infective periostitis.

By far the most important disease of the bone, and that for which excision has chiefly been practised, is sarcoma. It is as a rule impossible to determine the exact starting-point of the tumour; Butlin believes that it is usually subperiosteal. Sarcoma of the scapula is of rapid growth, and usually projects from the dorsal surface of the body of the bone.

The preservation of the arm after removal of the scapula is a matter of very considerable importance. The Surgeon who first ventured on the bold operation of **Removal of the Whole Scapula** was Cumming, in 1808. Gaetani Bey, in 1830, first amputated the arm and then proceeded to extirpate the shoulder-blade. In 1819 Liston removed the whole of the upper two-thirds of the scapula from a lad without sacrificing the arm. In 1828 Luke removed nearly the whole of the scapula from a girl of fourteen for malignant disease, sawing across the bone through its neck and the root of the acromion, and thus leaving the glenoid cavity and the acromion process. Hayman, Janson, Wützer, and Textor all performed similar operations, removing the greater part of the bone, but leaving the glenoid cavity and more or less of the parts above the spine. In 1837 Mussey (U.S.) excised the whole of the scapula and the clavicle for an enormous osteo-sarcoma; the patient, a man, was, according to Gross, in excellent health fifteen years after the operation. In 1850 Gross removed the whole of the scapula, with the exception of the glenoid cavity, by sawing through the neck of the bone, for an osteo-sarcoma weighing seven pounds. Indeed, the American Surgeons have distinguished themselves highly in this department of surgery. Thus, in 1838, McClellan removed the whole of the scapula with the clavicle for a soft sarcoma, but the patient died. In two cases Gilbert (U.S.) removed the scapula, half of the clavicle, and the upper extremity, one patient living a week, the other three months, after the operation. In 1845 Mussey successfully operated by the removal of the scapula, the outer half of the clavicle, and the upper extremity. In Gross's case, the only portion of the scapula left attached to the upper extremity was the glenoid cavity. In 1856 Syme went a step further in this direction, and, by disarticulating the bone instead of sawing through its neck, removed the scapula with all its processes entire from a woman seventy years of age, also leaving the arm untouched. Since that period complete removal of the scapula, leaving the arm untouched, has been done several times by Syme, Jones of Jersey, Cock, Fergusson, Pollock, Heath, Symonds and others. The arm so left becomes useful, capable of performing all the underhand movements, and of lifting considerable weights; and it may now be looked upon as an established rule in surgery that the limb should never be removed unless it also be the seat of disease, rendering necessary that addition to the excision of the scapula. Fergusson preferred sawing through the root of the acromion to disarticulating that process, so as to give greater roundness to the shoulder and preserve the attachment of the trapezius.

**Partial Excision of the Scapula** has usually been practised for tumours of the bone. The extent of bone requiring excision will necessarily vary greatly according to the size and character of the tumour, and the severity of the operation will mainly depend upon whether it is the upper or the lower portion of the bone that is the seat of disease. When the tumour is situated towards the lower angle of the bone, it may be exposed by a crucial or T-shaped

incision, and the body of the bone sawn through transversely below its neck and spine. A sarcoma of the inferior angle of the scapula, which was removed in this way by Marcus Beck, is preserved in the Museum of University College; the growth involves the origin of the *teres major*. In such cases the hæmorrhage need not be very great, as the main trunk of the subscapular artery, or even the dorsal artery of the scapula, is not necessarily divided. If the tumour spring from and be connected with the spine and acromion, only projecting forwards over the shoulder and leaving the rest of the bone sound and the joint unaffected, it may be freely exposed, the spine of the scapula sawn or cut across with bone-forceps, and the mass turned off from the point of the shoulder, without injury to the articulation or the implication of vessels of any importance.

When the tumour occupies the upper half of the scapula, the case is much more formidable, and the line of practice to be adopted must depend upon the parts involved. If the disease involve the body of the bone, encroaching upon the supra- or infra-spinous fossa, extending forwards into the axilla below the neck of the scapula, and thus coming into relation with the subscapular artery, it would be wiser to remove the whole bone, than to attempt the resection of the upper half, leaving only the lower angle, which would be useless to the patient.

When the body of the scapula is involved in a morbid growth, extending over the greater part or the whole of the subscapular or infraspinous region, and stretching forwards under the *latissimus dorsi* muscle into the axilla, the case becomes infinitely more serious, as not only must the whole of the scapula be removed, but the subscapular artery must be divided, and the axillary nerves and vessels brought into the field of operation. In these cases, also, the question as to the preservation or removal of the arm has to be considered. Whenever the joint is sound, and the upper part of the limb free from disease, it should be preserved; and, as these conditions usually exist where the disease originates in the scapula, the contemporaneous or antecedent amputation of the arm is seldom required.

**Operation.**—Excision of the scapula may be performed by exposing the bone freely by V-shaped, T-shaped or crucial incisions. The method most commonly adopted has been by the T-shaped incision. A long incision is made extending from the acromial end of the clavicle downwards along the axillary border of the scapula to the lower angle; from the middle or upper third of this a second incision is carried at right angles reaching to the posterior border of the bone, near the root of the spine. The flaps thus formed are dissected up and turned back, the trapezius being raised in the upper flap if it is not implicated in the tumour. The acromio-clavicular articulation, the outer end of the clavicle, or the base of the acromion is then cut through according to the extent of the disease. By feeling for the notch in the upper border of the scapula the situation of the suprascapular artery can be ascertained, and unless it is overlapped by the tumour it may at once be tied and divided. The posterior scapular may be now sought for by carefully dividing the *levator anguli scapulæ*, beneath which the main trunk will be found, and may be secured. An assistant can then force his finger forwards in the upper and outer angle of the wound, and compress the subclavian artery against the first rib. The muscles attached to the posterior border may then be divided, the *serratus magnus* being cut as close as possible to its insertion, and the hand

passed to the ventral aspect of the bone, which is thus drawn forcibly backwards and outwards. The muscles attached to the coracoid process may then be divided or the process sawn through at its root. The whole bone can now be drawn still further outwards, and the joint opened from the inner side by dividing the subscapularis close to its insertion. The disarticulation is then completed, and the remaining muscles divided, the knife being kept as close as possible to the bone so as to avoid wounding the main trunk of the subscapular. The posterior circumflex is in danger of being cut as the long head of the triceps is divided unless the edge of the knife be turned away from it. The *teres major* should be cut near its attachment to the scapula.

In this operation the hæmorrhage is necessarily copious, and may be dangerous, but by compression of the subclavian artery after the early stages of the operation, and the immediate application of forcipressure-forceps (two dozen of which at least should be at hand) to every bleeding point, it can usually be kept well under control.

After the operation the flaps must be laid down and retained in position by sutures, free drainage being provided by means of tubes.

**Result.**—Of 45 cases of complete removal of the scapula collected by Poincot in 1885 Butlin has abstracted 25 in which the operation was undertaken for tumours, which were probably or certainly malignant, as follows:—"Two deaths due to the operation; two deaths within a very short period of the operation, probably in both cases due to disease of the internal organs; eleven deaths due to recurrence of the disease or to affection of the lungs; one recurrence in less than two years, which necessitated amputation of the upper extremity; three patients lost sight of shortly after recovery from the resection; four patients said to have been cured, but without any information of the permanence of the cure; two cures of eighteen months and six years respectively, but with great uncertainty whether the disease was really malignant in the former of the two cases." Of the whole 45 cases the mortality from the operation was about 10 per cent. In successful cases the subsequent utility of the arm has often been very good: thus in Symonds's case the patient was doing his work as a carpenter, including the use of the plane, two and a half years after the operation.

#### DISEASES OF THE SHOULDER-JOINT.

Synovitis of the shoulder frequently occurs as the result of rheumatism and injury; rheumatoid arthritis is common, but tuberculous disease is comparatively rare. The latter usually commences as a deposit in the upper extremity of the humerus, and, as we have already seen, not unfrequently assumes the form of dry caries. There is, therefore little or no swelling, and the roundness of the shoulder is lost as the result of the atrophy of the deltoid. The chances of spontaneous cure are considerable, with more or less fixation of the joint. When an abscess forms it may come forwards into the bursa beneath the tendon of the subscapularis, or it may escape from the joint along the tendon of the biceps, or extend backwards to the posterior border of the deltoid.

In cases of tuberculous disease it may be doubtful whether the shoulder-joint itself is actually involved. In such cases, by carefully opening the abscess, a sequestrum may sometimes be removed from a carious cavity in the head of the humerus, without the necessity of excising the joint. Acute

necrosis of the upper part of the shaft of the humerus is common, and the appearance of the part when sinuses are present may closely resemble that of joint disease. In removing the sequestra care must be taken not to open the joint, and the incisions must be planned with due regard to the musculospiral nerve.

In the majority of cases in which operation is necessary for tuberculous disease of the shoulder excision of the head of the humerus is required, but should the Surgeon on opening the joint find the bones healthy he will probably be justified in removing the diseased synovial membrane as completely as possible, and making an endeavour to save the head of the bone. Cases also occur in which the latter is so little affected that a partial removal or division through the anatomical neck may be practised instead of complete removal below the tuberosities.

**Excision of the Shoulder-Joint for Disease.**—In addition to tuberculous disease the head of the humerus has been excised for sarcoma, but this operation is not usually advisable in such cases. Bickersteth has successfully removed the head of the humerus for exostosis. In cases of intracapsular fracture through the neck of the humerus, with detachment of the head of the bone, disorganization of the joint has resulted. The joint has been laid open, and the loose head of the bone removed in two instances by Brainard of Chicago; the patients recovering with useful limbs.

**Operation.**—**Partial Excision** of the head of the humerus in some cases of caries has been practised by slitting up sinuses and the application of the gouge or sharp spoon to the diseased osseous surface. Occasionally, as in cases reported by Fergusson and Sédillot, these operations have been attended with successful results. But not unfrequently they fail to effect a cure, the disease extending, and the sinuses not healing, so that eventually excision of the whole of the diseased head of the bone has been required.

**Complete Excision** of the head of the humerus is the operation usually required. It may be practised in several different ways, the lines of incision through the soft parts being varied according to the conditions of the case. They are most commonly made on the front or outer side of the joint through the deltoid muscle, but in exceptional cases the head of the bone may be removed from behind. Excision may be performed by the single longitudinal, or its modifications the  $\Gamma$  or  $\top$ -shaped incision, or by a U-shaped incision or flap-operation.

The operation by the **single longitudinal incision** may be performed as follows. The patient lying on his back, with his shoulder slightly projecting over the edge of the table, the Surgeon enters the knife to the outside and above the coracoid process, about half an inch below the clavicle, and carries it directly downwards for from three to four inches, stopping immediately above the insertion of the pectoralis major. The first incision should divide the skin and fat, and pass through the anterior fibres of the deltoid, so that when the wound is held open the capsule of the shoulder-joint comes into view. This incision is immediately external to the cephalic vein, which should not be wounded, and divides no important artery or nerve. The wound being now held open with blunt hooks or copper spatulæ (Fig. 548), the bicipital groove should be felt for between the great and small tuberosities of the humerus. A longitudinal incision is then made firmly on to the bone along the inner side of the groove, dividing the periosteum covering the head of the bone, and the

capsule as far as the margin of the glenoid cavity. If the long tendon of the biceps be still undestroyed by the disease it must be turned out of the groove and held to the outer side in a blunt hook. The assistant then rotates the arm forcibly outwards, so as to bring the small tuberosity well into the wound, and the Surgeon separates the tendon of the subscapularis and the periosteum from the bone with a periosteal elevator. In most cases of disease of the joint this can be done without great difficulty, as the adhesion of the tendon to the bone is loosened by the inflammation. Should the adhesion of the tendon be too firm to allow of its being stripped off with the elevator the knife must be used, but care should be taken to shave the capsule off in such a way as, if possible, to leave it still connected with the periosteum covering the upper part of the humerus. The arm then being rotated inwards, and the limb allowed to fall over the edge of the table, the three muscles inserted into the great tuberosity are separated from the bone in the same way as the subscapularis. During this part of the operation the biceps tendon must be drawn to the inner side with a

Fig. 248. — Excision of Shoulder-joint. Longitudinal Incision.

Fig. 249. — Stump after Amputation at Shoulder-joint by Spence's method.

blunt hook. The assistant then forces the head of the bone up into the wound whilst the Surgeon separates the posterior part of the capsule with an elevator, leaving it attached, if possible, to the periosteum below. He now takes the limb in his own hands, and having the soft parts well retracted, he pushes the head of the bone out of the wound so as to allow the easy application of the saw by which it is removed. Should the parts around the head of the bone be thickened, and unyielding, more space may be gained by making a short cross cut at the upper end of the longitudinal incision, and thus converting it into a modification of the  $\Gamma$  or  $\Upsilon$ . By this method of operating, the posterior circumflex artery and the circumflex nerve are not divided, and but few vessels will be found to require ligature. The fibres of the deltoid are little interfered with, and if the incision be not carried too low, the insertion of the pectoralis major will be at most only partially cut through. It is recommended by some Surgeons to make a small opening behind through which a drainage-tube can be passed, emerging a little below the acromion. In doing this care must be taken to keep well above the posterior circumflex artery. By this

means drainage is certainly facilitated, and the healing of the anterior wound is hastened.

Should the extent of the disease or injury prove to be so great as to require amputation of the limb, this may readily be done, as was suggested by Spence of Edinburgh, by carrying the knife round the inner side of the limb, and so detaching the member, with due attention to those points in connexion with the axillary artery that have been described in Vol. I., p. 110. The result, as seen by the annexed drawing (Fig. 549), is very satisfactory.

The **elliptical operation** of excision may be performed in the following way. A curved incision is made, commencing at the posterior part of the acromion, reaching downwards to the insertion of the deltoid, and terminating at the outer side of the coracoid process. By a few touches of the scalpel, a large flap composed of the deltoid muscle may thus be raised, and the diseased articulation fully exposed. As in the operation just described, an attempt

Fig. 550.—Excision of Shoulder-joint. Elliptical Incision.

should be made to save the capsule and maintain its connexion with the periosteum. For this purpose a longitudinal incision should be made through the capsule, and it should be stripped off with the tendons and periosteum by means of the periosteal elevator, aided by the knife when necessary. The head being pushed out may then be removed with a narrow saw. The shaft of the humerus should be encroached upon as little as possible, so that the arm may not be shortened more than is necessary. After the operation, the flap must be retained in position by sutures, and a drainage-tube inserted behind.

After the removal of the head of the bone, the glenoid cavity must be examined. If this be merely superficially carious it may be let alone, but should it be more deeply implicated, with cavities hollowed out in it, perhaps containing sequestra, the diseased bone must be thoroughly removed by means of the gouge and sharp spoon.

When the sinuses open entirely behind it is possible to excise the joint by

an incision made through the posterior fibres of the deltoid, commencing immediately below the root of the acromion, and carried downwards for an inch and a half or two inches, but not so low as to endanger the circumflex nerve and artery. The space thus obtained is limited, and does not allow of a methodical subperiosteal excision being performed as above described, but in most cases the capsule is softened by the disease, and the adhesion of the tendons so far loosened that there is no difficulty in forcing the head of the bone out of the wound. This operation has been performed with the best results by Christopher Heath in University College Hospital.

After excision of the joint, the arm must be well supported in a sling, the elbow especially being raised. A pad should be placed in the axilla to prevent the tendency of the pectoralis major, teres major, and latissimus dorsi to draw the arm inwards. The union, which is by granulation, is usually slow.

**Result.**—The shoulder-joint in its normal condition possesses five distinct movements: 1. Rotation; 2. Abduction and Elevation; 3. Adduction; 4 and 5, movements in the antero-posterior direction. The most useful movements are those of abduction, and the two in the antero-posterior direction. These are requisite in all ordinary trades and for the guidance of the hand in most of the common occupations of life. The movements of elevation are seldom required, except by those who follow climbing occupations, as sailors, bricklayers, &c. Now the mode of performing the operation, as well as the operation itself, will materially influence these different movements. Thus, if the deltoid be cut completely across by an elliptical incision, and the circumflex nerve divided, the power of abduction of the arm and of its elevation will be permanently lost. If its fibres be merely split by a longitudinal incision (Fig. 548), they may be in great part preserved. The movements of rotation, &c., which are dependent on the actions of the muscles that are inserted into the tuberosities of the humerus, are usually permanently lost; for in most cases of caries of the head of the humerus requiring excision, the Surgeon will find it necessary to saw through the bone below the tuberosities—in its surgical, and not in its anatomical neck. Hence the connexion of the supraspinatus, infraspinatus, and teres minor, and the subscapularis to the bone will be separated. Should the Surgeon however succeed in maintaining the connexion of the capsule of the joint and the tendons with the periosteum by adopting the subperiosteal method of operating above described, the divided tendons may form new attachments to the humerus, and the muscles retain their functions in a greater or less degree. Those muscles which adduct and which give the antero-posterior movements, viz., the coracobrachialis, the biceps, the pectoralis major, latissimus dorsi, and teres major, will all be preserved in their integrity; and hence it is that the arm, after this excision, is capable of guiding the hand in so great a variety of useful under-handed movements. In the case of a man whose shoulder-joint I excised many years ago, I last saw the patient about fifteen years after the operation had been performed; the upper end of the humerus had been drawn up underneath and between the acromion and coracoid processes, where a false joint had formed. The arm was extremely useful, and all the parts below the elbow were well developed. The upper arm was shortened by two and a half inches.

Excision of the shoulder-joint is on the whole a very successful operation, as regards life as well as limb. Hodges has collected 50 cases of excision of

the head of the humerus for disease : of these, 8 died and 42 recovered from the operation. Of the 8 deaths, 3 only occurred before the third month, and 3 were from phthisis. In 2 only did death appear to have been directly occasioned by the operation. In but 17 of these 50 cases was the glenoid cavity interfered with ; but it is a remarkable circumstance that in no fewer than 7 out of the 8 fatal cases this cavity was diseased, and was treated by gouging, excising, or cauterization.

**Excision for Compound and Comminuted Fracture.**—When excision of the shoulder-joint is required for compound and comminuted fracture from gunshot injury, the operation is of a less formal character. The bullet-wounds must be laid freely open in a longitudinal direction, or the deltoid even cut across at its superior attachment, all loose splinters removed, and the ragged ends of bone cut off with forceps or a narrow saw ; especial care being taken in manipulating towards the inner and under sides of the joint, in the vicinity of the large nerves and vessels. Without going back to the earlier cases of Percy, Larrey, and other military Surgeons of the latter part of the last century, who frequently practised this operation with the happiest results, the more recent experience of the wars in Europe and America demonstrated its great utility, and that it ought invariably to be preferred to amputation at the shoulder-joint in all cases in which the large blood-vessels and nerves are intact. Hodges states that in 96 recorded cases from all sources there were 25 deaths, or a mortality of 26 per cent. But in the Crimean war the result was much more satisfactory. Thus Bauden relates 14 cases occurring in the Crimea, with only 1 death ; and in the British army, of 14 cases, 12 recovered ; whilst of 60 amputations at the shoulder-joint 19 were fatal. In the American war, the mortality in 575 cases of excision of the shoulder-joint was at the rate of 32·5 per cent. Primary excisions were more successful than secondary : the percentage of mortality in the former (252 in number) being 23·3, and in the secondary (393 in number) 34·6.

#### DISEASES OF THE ELBOW-JOINT.

The only affection of the elbow which requires special mention is **tuberculous disease**. This may commence either in the synovial membrane or in one of the bones, but the cases in which the joint is secondarily infected from a primary osseous deposit are undoubtedly the more common. This tuberculous deposit most frequently occurs in the olecranon process of the ulna, but the humerus is sometimes first affected, and less frequently the radius. The cases of primary synovial disease are more common in children than in adults. The first symptom of the disease is usually painful and restricted movement, the limb being held in a flexed position. Swelling is first detected in the hollows between the olecranon and the condyles of the humerus, or over the radio-humeral articulation. Gradually the enlargement assumes a fusiform shape, and is the more obvious on account of the wasting of the muscles of the arm and forearm. Abscesses may form in any position around the joint and often burrow for a considerable distance before bursting. Finally, the swelling may subside and ankylosis slowly supervene, numerous sinuses around the joint continuing to discharge for long periods. In some cases of primary bone disease the swelling of the surrounding parts is not great, and one or more

sinuses lead down to carious or necrosed bone in the olecranon or the condyles, the joint being permanently flexed and the arm useless.

The *Treatment* of tuberculous disease of the elbow in its early stages consists in complete fixation at right angles with the hand in the mid-position between pronation and supination. Until the last few years the routine treatment in cases requiring operative interference consisted in complete excision of the joint. Recently, however, good results have been obtained in suitable cases, by applying to the elbow the same principle of treatment that has been so successfully employed in the knee, viz., to open the joint and remove the diseased tissues as completely as possible without unnecessarily sacrificing healthy structures.

**Arthrectomy** of the elbow may be done by different methods, but the two which will be found most generally useful are : 1, two lateral incisions ; and 2, a single longitudinal posterior incision with temporary resection of the olecranon. If lateral incisions be employed, they must be made over the intervals between the condyles and the olecranon ; on the inner side the ulnar nerve must be carefully preserved, and on the outer side the incision must not be carried too low lest the posterior interosseous nerve be wounded. If temporary resection of the olecranon be practised the process may be divided at its base with a saw or chisel, and subsequently re-adjusted with a stout silver-wire suture. In any case when the joint has been opened the tuberculous synovial membrane is thoroughly removed with forceps and scissors ; at the same time any loosened or partially eroded cartilage is cut away, and diseased foci in the bones thoroughly scraped. The incisions should be closed with sutures except at the extremities which are left open for drainage, and the subsequent management of the case will be the same as after excision. The treatment of tuberculous disease of the elbow by arthrectomy instead of by formal excision has been specially advocated in this country by Cheyne and Clutton. Of nine cases treated in this way by Clutton, recovery with useful movement followed in six ; in two ankylosis occurred, and in the remaining case excision was subsequently required.

**Excision of the Elbow.**—In tracing the history of the introduction of this operation into surgical practice, we find, as is the case in several other parts, that it was first partially and then wholly done for injury, and proposed by one Surgeon and eventually practised by another for disease. Thus in 1758 or 1759, Wainman, in a case of compound dislocation of the joint, sawed off the lower end of the humerus just above the fossa, leaving the patient with a flexible and useful arm. Tyre, of Gloucester, did the same, removing two and a half inches of the lower end of the humerus, in a case of compound dislocation. Justamond, of the Westminster Hospital, was the first to operate in a case of disease : this he did in 1775, removing the olecranon and two inches of the ulna. Park proposed, but did not have an opportunity of practising, the complete excision of the joint. This was done for the first time by Moreau, senior, in 1794, and again by Moreau, junior, in 1797. Little was done from this time until the operation was revived by the Surgeons of Leeds ; in 1818 by Stanfield, in 1819 by Chorley and Hey. It then made rapid progress, and was specially practised by Syme and Liston, and the Surgeons of the Edinburgh Infirmary.

This operation may be required, 1, for Chronic Disease of the Joint ; 2, for Osseous Ankylosis ; and 3, for Compound Fractures and Dislocations.

1. **Excision** is required in cases of *tuberculous disease* if the bones are extensively affected or if recurrence has taken place after arthrectomy has been performed. In young children especially complete excision must, if possible, be avoided, and except in neglected cases is rarely necessary. In some cases also excision is required for *acute destructive arthritis* secondary to suppuration taking place outside the joint and extending into it. The elbow forms an exception to the rule that excision of a joint is not to be undertaken while there is a hope of obtaining a cure by ankylosis. Provided

Fig. 551.—Excision of elbow-joint. Sawing the humerus.

the patient is otherwise healthy, the operation may be performed as soon as it is evident that the movements of the joint will be lost should recovery take place under simple treatment.

2. If *osseous ankylosis* have occurred, whether in the straight or in the bent position, excision may advantageously be practised, provided the patient is in good health. This operation was first performed in 1827, by Rhea Barton of Philadelphia. When the elbow is ankylosed in the straight position, the arm is quite useless; and any operation by which flexion of the limb can be obtained, will add materially to the patient's comfort, rendering the hand available for

most purposes of life. In cases of *angular osseous ankylosis* of the elbow, a wedge-shaped piece of bone should be removed.

3. In cases of *compound fracture or dislocation* of the elbow-joint, more or less complete resection of the protruding, and possibly splintered fragments, may be required (Vol. I., pp. 594 and 680).

**Operation.**—Excision of the elbow-joint may be performed by the **H**, the **T**-shaped, or the simple longitudinal incision, or by two longitudinal incisions. Each method has its advocates. The **H**-shaped operation consists in making an incision parallel to, and a little to the radial side of, the ulnar nerve, another along the outer side of the joint, and uniting the two by a cross cut, dissecting up and down two square flaps, and cleaning the bones laterally. It was soon found by Surgeons that by this method a very unnecessary amount of incision was practised; and accordingly the vertical cut along the outer side was dispensed with, and the **—**-shaped operation adopted. This consists in making the longitudinal incision parallel to, and a little to the radial side of the ulnar nerve, and the cross cut over the olecranon to the outer side of the joint. Subsequent experience has shown that this incision may be still further simplified, and the operation reduced to a single longitudinal incision carried over the centre of the joint in the middle line from above downwards. In comparing these different methods of operating, I decidedly give the preference to the single longitudinal incision, as being quite sufficient in all ordinary cases for the complete and easy removal of the articulation. Both the **H**- and **T**-shaped incisions involve, moreover, a complete transverse division of the tendon of the triceps, in consequence of which the power of active extension of the limb may be lost after recovery from the operation. Should the soft structures towards the outer side of the joint not yield sufficiently, a cross-cut can at once be made, so as to liberate them, and give the Surgeon more room, by turning up the two triangular flaps that will thus be formed.

The following are the successive steps of the operation by the **T**-shaped and single longitudinal incisions. Should the former be adopted, either in consequence of the situation of the sinuses or of previous incisions for the relief of abscesses, the arm being held across the chest, the perpendicular cut should be made parallel to, and a line or two to the outer side of, the ulnar nerve; being commenced at least two inches above the point of the olecranon, and carried down to about three inches below it. The transverse incision may then be made directly across the end of the olecranon, to the outer side of the joint, and extended as far as the extremity of the outer condyle (Fig. 552). The two triangular flaps thus made must be dissected up, the knife being carried close to the bones (Fig. 553). The subsequent steps are the same in the operation by the single longitudinal incision.

In the operation by the *single longitudinal incision* the arm is held in the position just described, and the incision is commenced from two to three inches below the tip of the olecranon and carried directly over the middle of that process, terminating a similar distance above it. If the parts are much swollen, the length of the incision must be increased so as to allow of the sides being held well apart. The incision must be carried firmly down to the bones so as completely to divide the tendon of the triceps in a longitudinal direction. The arm is then slightly extended, and soft parts cleared from the inner side of the joint. To do this the thumb must be pushed into the longitudinal slit in the triceps, and the tendon thus put on the stretch and shaved

away from its attachment. If the periosteum is swollen and loosened by inflammation, this may be wholly or in part done with a periosteal elevator, and the connexion between the tendon and the periosteum may be preserved; more commonly, however, the knife has to be used. After the triceps is separated, the remaining soft parts must be carefully turned off the inner side till the internal condyle comes into view. In doing this the edge of the knife should always be kept against the bones, or the periosteal elevator may be used, so that the ulnar nerve may be turned over the inner condyle without injury. If the incision be properly made and the knife kept in contact with the bone, the nerve ought not to be exposed during the operation, more particularly as it is usually embedded in the inflamed tissues surrounding it. When the inner side of the joint has been sufficiently cleaned the soft parts must be turned back in the same way on the outer side. In doing this it is very important to save uninjured the strong tendinous expansion that passes from the triceps over the

Fig. 552.—Excision of Elbow-joint: T-shaped Incision.

Fig. 554.—Excision of Elbow-joint by Longitudinal Incision.

Fig. 553.—Excision of Elbow by T-shaped Incision. Bones exposed. Ulnar Nerve indistinctly seen.

surface of the anconeus, to be attached to the posterior border of the ulna. If this be preserved, the connexion between the triceps and the ulna is maintained, and the patient will regain the power of active extension of the joint when recovery has taken place. When the posterior part of the joint has thus been laid bare, the tip of the olecranon should be removed by cutting forceps, so as to give free access to the articulation. The limb is next flexed forcibly till the forearm touches the arm, the humerus being held vertically at right angles to the table; the forearm is at the same time pulled towards the table. The lateral ligaments being then divided by a touch of the knife, the articular surface of the humerus projects from the wound, and can be removed by a narrow saw cutting from the anterior surface. If the sawn inner condyle form too sharp a point, a small piece may be removed with the bone-forceps. The bones of the forearm are then forced out of the wound by the assistant and cleaned with the elevator or knife till the cartilage-covered surfaces are sufficiently exposed to be removed by the saw. The brachial artery is so com-

pletely protected by the brachialis anticus that it could not easily be wounded, but if there is much pulpy swelling of the synovial membrane it will sometimes be found useful to press a copper spatula between the humerus and the bones of the forearm to facilitate the exposure of their ends for sawing. The ulnar nerve is in danger while the inner side of the ulna is being cleaned for the saw, and sometimes during the sawing of the bone, and it must therefore be guarded or drawn on one side by a bent copper spatula or a blunt hook. Should any sinuses exist, especially towards the inner side of the arm, they had better be left untouched. I have more than once known the ulnar nerve cut across by the Surgeon in laying open what appeared to be very superficial sinuses in this situation.

In this operation it is of great consequence, so far as the after utility of the arm is concerned, not to remove more of the bones lengthwise than is absolutely necessary. The shaft of the humerus, for instance, should never be encroached upon; it will be quite sufficient to limit the excision to the articular surface. Should any carious portions of bone extend beyond this, I think it is better to scoop them out with the gouge than to remove them in any other way. The excision of the ulna and radius should not be carried so low as to divide the insertions of the brachialis anticus and biceps. After opening the articulation, a practical question of considerable importance often arises; viz., to what extent the resection of the articular ends should be carried. If they be all diseased, there can of course be no doubt as to the propriety of removing the ends of the three bones. So, also, if the humerus and ulna be diseased, the head of the radius should be cut off on a level with the section of the ulna. But the important point is, whether, in the event of only one bone being implicated, by disease or injury, the Surgeon should limit himself to the excision of this alone, or should remove the other two. Formerly, in accordance with the principle of conservative surgery, that diseased or injured parts alone should be sacrificed, I have advocated leaving the healthy articular ends, and only removing that which was diseased; but increasing experience has convinced me that the practice is erroneous, and that, if the joint be only partially excised, ankylosis, or return of the disease in the bones, is very apt to ensue. I would therefore advise that in all cases, the whole of the articulation be removed, as well as in those cases in which operation is required in consequence of comminuted and compound fracture of only one of the bones; as, for instance, when the lower epiphysis of the humerus, or the upper end of the ulna only, is the seat of such injury. In excision of the elbow for osseous ankylosis, a piece of the united bones about an inch in length should be sawn out; the cuts should be made at right angles to the shafts of the bones, and the piece removed must include equal portions of humerus and of ulna.

The operation by *two lateral incisions* has been recommended by Hueter and others. The advantages claimed for this method are that it saves to some extent the injury to the triceps involved in the other methods, that it provides better drainage, and that the scars are left at the lateral aspects of the new joint instead of behind. The inner incision should be the shorter, and should be made first, the ulnar nerve being turned out of its groove and the internal lateral ligament of the joint divided. The outer incision should be of considerable length, and should pass close to the radial border of the olecranon. Hueter recommends that the external lateral ligament should be divided and

the head of the radius removed first. The lower end of the humerus can then be dislocated and forced out at the external wound, or sufficiently exposed to be safely sawn with a narrow-bladed saw ; after which the olecranon and the upper end of the ulna can be cleaned with the elevator, protruded from the wound, and removed.

In all methods of operating it is generally recommended to save as much of the periosteum as possible. Ollier states that the results obtained by subperiosteal resection are far better than those by the older methods. In practice it will be found that, in excision for disease, whether the knife or the periosteal elevator be used, if the rule of keeping the instrument close to the bone be followed, the greater part of the periosteum will be saved, as its adhesion is always loosened by the inflammation. In primary excisions for injury, on the other hand, the greatest care must be taken to save the periosteum, otherwise a flail-like joint is very apt to result.

In many cases of excision of the elbow no vessels require ligature, though there may be free general oozing. I have never seen troublesome bleeding. After the operation the wound may be closed with sutures and treated according to the rules already laid down (p. 376).

Much of the success in the result of the excision of this, as of other joints, will depend upon the care and attention bestowed on the after-treatment of the case. The object of the treatment is to obtain a strong false joint possessing all the natural movements of the elbow. In order to do this a somewhat different course of treatment must be adopted in different cases. In all excisions for disease, we have to guard against ankylosis ; undue mobility is very rare, and I have never seen it. In primary excisions for injury, a flail-like joint is not uncommon, especially if much bone has been removed and the periosteum not preserved. I have met with it in one case—that of a young woman, the lower end of whose humerus was completely disorganized and the elbow-joint opened by a fall. In this case the lower epiphysis of the humerus was excised, together with the articular ends of the ulna and radius. A good recovery took place ; but, although every care was taken to support the limb on splints, a very movable joint was left. In excisions for disease, or for the secondary results of wounds, we may in most cases dispense with splints. After the operation, the limb may be laid upon a pillow nearly in the extended position. Some of the Edinburgh Surgeons have recommended that the limb should be placed in the fully extended position with a very gentle weight extension applied to the wrist to prevent the bones from coming in actual contact with each other. This treatment has been tried in University College Hospital, and found to be very comfortable to the patient. At the end of a week or ten days passive movement must be commenced. In doing this, care must be taken not to grind the bony surfaces against each other ; gentle extension must be maintained while the angle of the limb is altered. At first it is sufficient merely to alter the position of the limb, letting it lie in the flexed position one day and in the extended the next. As the wound heals more extensive movements may be carried out daily. Pronation and supination must not be neglected, and in carrying out these movements the ulna must be held steady with one hand while the radius is rotated on it by the other hand. The pain accompanying passive movement is much less if it be commenced early than if it be delayed till fibrous union between the bones has taken place. Splints are required only if there should be any tendency to displace-

ment immediately after operation, if more than the usual amount of bone has been removed, or if there should be any tendency to excessive looseness of the new joint after the third week. The patient can usually leave his bed at the end of the second week, and the arm must then be carried in a sling. It is deserving of notice that after arthrectomy of the elbow Clutton has altogether abandoned passive movement, keeping the joint absolutely fixed during the healing, with good results.

In primary excisions for injury, a properly-constructed splint is frequently required for some weeks, as the tendency is usually towards a flail-like, fibrous union rather than to ankylosis. A splint jointed opposite the elbow will be found useful in many cases so as to allow of variation of position when necessary. Pronation and supination must not be neglected, and must be made when the splint is removed, as no apparatus has yet been invented which will allow of these movements being carried out in a normal way whilst it is applied.

By the above mode of treatment a useful false joint can almost always be obtained. In two cases which I have had the opportunity of dissecting, one sixteen months and the other two years and a half after the operation, it was

Fig. 555.—Arm after Excision of Elbow.

found that the ends of the bones were rounded and firmly held together by a capsule of dense ligamentous tissue. In this way a most useful limb will result, having the four movements of flexion, extension, pronation, and supination nearly perfect, with but little deformity, as may be seen by the accompanying cut (Fig. 555),

which was taken nearly two years after operation from a patient of mine. A coachman, whose elbow-joint I excised, was able to drive, to lift a pail of water, and to do all the duties of his employment, nearly as well as if the arm had retained its normal condition.

Should there be any danger of ankylosis, the patient may be put under chloroform and forcible flexion and extension employed; after which, passive motion must be kept up daily. If this fail care must be taken that the ankylosis occurs in a flexed position.

Should recurrence of disease take place, resection may again be resorted to with success. In one case, indeed, which had been unsuccessfully operated on twice by other Surgeons, I excised the bones about the elbow for the third time with complete success, removing a considerable portion—nearly three inches—of the necrosed shaft of the humerus, and the carious upper ends of the radius and ulna. In this case, which was that of a boy about fourteen years of age, complete recovery took place. He had a most useful arm, regaining the four movements of the joint, pronation, supination, flexion, and extension, and this notwithstanding his being of a most strumous habit. Six months after the excision amputation of the thigh was performed for disease of the femur, and he eventually died at the end of two and a half years, of caries of the spine.

**Results.**—Excision of the elbow-joint, as far as life is concerned, is a very successful operation. The result, when it is practised for compound fracture

or dislocation, has already been stated in Vol. I., pp. 590 and 680. When practised for disease it is equally satisfactory; and indeed death can occur only from some accidental complication, such as may follow any operation. I have lost only one patient out of very many in whom I have excised the elbow-joint. The principal danger after this operation arises from diffuse suppuration in the medullary canal of the humerus. I have seen this happen in two fatal cases in the practice of others, pyæmia developing in both instances; and in a third, in which the patient lost his life, it is probable that death, which was attributed to pneumonia, occurred from the same cause.

## DISEASES OF THE RADIUS AND ULNA.

The various inflammatory diseases to which bones are liable occasionally affect the radius and ulna. Syphilitic nodes are sometimes met with on the subcutaneous border of the ulna, and extensive tuberculous caries of either bone may occur. Acute necrosis is much less common than in the humerus.

Fig. 556.—Arm from which Radius has been removed.

Fig. 557.—The Radius after Removal.

Sarcoma of these bones is rare; when central it generally involves the lower end. When the disease is subperiosteal, amputation should be performed through the elbow-joint or in the lower third of the arm, but in the treatment of a central tumour resection of the affected portion of the bone may be practised. In a case of myeloid sarcoma of the radius which had become adherent to the ulna, Morris successfully performed partial resection of both bones, the radius being divided below the insertion of the supinator brevis; a very useful limb resulted.

Complete excision of one or other of the bones of the forearm has occasionally been practised with advantage, leaving a sufficiently useful limb with good power in the hand. Carnochan of New York and Jones of Jersey have successfully excised the whole ulna. In a case recorded by Weist (U.S.), nearly the whole ulna was removed on account of a gunshot wound. Care was taken to preserve as much as possible of the periosteum; and reproduction of the bone, forming a very useful limb, had taken place at the end of a year. Batts of Virginia has removed the whole radius. In a woman who was under my care about twenty years ago, I also successfully resected the whole radius, with the exception of its articular head, which was sound (Fig. 557); and a

useful arm, of which the annexed figure is a good representation, was (Fig. 556). After a time the hand gradually inclines towards the radial side of the arm ; but, although the articulation between it and the forearm is but a slender one through the medium of the ulna, a very useful member will be kept. These operations do not require any specific rules for their performance ; the bone is exposed by a long incision in the direction of, and made by slitting the sinuses that burrow amongst the muscles, and is then carefully dissected out from the parts amongst which it lies ; especial care being taken to preserve the periosteum and any new bony deposits that may already have been formed. In one case in which the elbow-joint was involved, and the radius diseased instead of amputating the limb I obtained an excellent result by excising the articulation as well as of the affected bone. The patient, a builder about thirty years of age, was able, four years after the operation, to use his hand not only for all the ordinary purposes of life, but also in his trade.

The **Olecranon** has been successfully removed in some instances ; for example, by Birkett of Guy's Hospital ; and on account of non-union after fracture by Newman of Stamford. In each case a useful arm was retained.

#### DISEASES OF THE WRIST-JOINT.

**Tuberculous disease** of the wrist is more common in adults than in children. Watson Cheyne believes that the disease is often primarily synovial and that when it commences as an osseous deposit, this is usually in the lower end of the radius or in the base of one of the metacarpal bones, especially the second and third. Although the disease rarely begins in the carpus, this is usually secondarily affected through its synovial cavities. It is an important fact that in tuberculous disease of the wrist the surrounding tendon sheath may become extensively affected, whilst in other cases the primary disease seems to be a tuberculous teno-synovitis, the joint being involved secondarily. In some instances also the joint disease has followed chronic effusion into the sheath of the flexor tendons, the so-called "compound ganglion." In these cases the distended sheath has contained melon-seed bodies, a condition which is itself in all probability often tuberculous.

In cases of tuberculous disease of the wrist requiring operative interference, excision has given good results in adults. In children, as we have seen, the disease is rare and should be treated as far as possible by partial operation. Amputation will sometimes be found necessary when the disease is very extensive or when recurrence has occurred after excision.

**Excision of the Wrist** formerly found less favour with Surgeons than the removal of other joints. The objections raised to it were, first, that it carries of the carpus the disease very often extends rapidly, with great constitutional disturbance, to all the small bones that enter into its formation, consequently partial operations rarely succeeded in curing the disease ; secondly, that owing to the superficial character of the articulation, and its close connexion with the flexor and extensor tendons, methodical operations by the older methods were almost invariably followed by a stiff and useless hand. Further experience has, however, shown that complete excision of the carpus with the lower ends of the bones of the forearm, and the bases of the metacarpal bones, may in suitable cases be undertaken with a good prospect of preserving a useful hand. I had a case in 1858, in the person of a middle-

in whom the whole carpus and a portion of the bases of the metacarpal were removed, and who recovered with a very useful hand, with some of flexing and extending the wrist, and with very considerable mobility of the fingers. To Lister, and to West of Birmingham, however, is due the credit of proving the practicability of the operation. The mode of operating described by the former of these Surgeons will be described here. But before giving the details of this operation, it may be well to mention the principles on which it is founded. On looking at the movements of the wrist-joint, it will be seen that they are somewhat limited in extent, so that if tolerably firm ankylosis can be obtained between the lower ends of the radius and ulna and the upper ends of the metacarpal bones, the normal amount of movement is maintained. Should these movements be lost or should the union be so loose as to necessitate the application of a rigid apparatus to support the wrist, the hand may still be perfectly useful, the lost movement of the wrist being supplied by those of flexion and extension at the elbow. But the hand cannot be useful if the flexion and extension of the fingers be seriously interfered with. An essential principle of Lister's operation is to preserve uninjured all the tendons concerned in the movements of the thumb and fingers. If we look at the tendons that surround the wrist, we shall find them divisible into five groups: 1. Those special to the thumb; 2. The extensors of the fingers; 3. The flexors of the fingers; 4 and 5. The extensors and the flexors of the wrist. Now the incisions are so planned as to save the whole of the first three groups, and to divide only the tendons of the wrist proper, and these are cut so as to their insertions that as a rule they form new attachments and resume their functions as recovery takes place.

**Lister's Operation.**—From the result of two cases of severe injury to the wrist-joint, which recovered with useful hands, Lister was led to the conclusion that, with proper after-treatment, the tendons about the wrist might be freely handled without permanent stiffness resulting. At the same time, he hoped by removing the whole of the cartilaginous surfaces to be able to prevent recurrence of the disease—which is the common ending of cases of partial excision of the wrist-joint for caries of the carpus. At the time when he published his papers, he had performed the operation of excision of the wrist fifteen times. The method of operating was essentially the same in all, various small details being altered as experience suggested. The operation, as he now performs it, is done as follows. Esmarch's bandage and anæsthetic should be applied, as without them the oozing of blood interferes considerably with the operation. Any adhesions of the tendons then existing should be forcibly broken down by moving the joints. An incision is now made on about the middle of the dorsal aspect of the radius, on a level with the styloid process, downwards and outwards towards the inner side of the carpo-phalangeal articulation of the thumb; but, on reaching the line of the radial border of the metacarpal bone of the index finger, it is carried downwards longitudinally for half the length of that bone." This incision should commence in the angle formed by the tendons of the common extensor of the thumb and the extensor longus pollicis, and the upper part should run parallel to the latter tendon, but without injuring it. The tendon of the extensor carpi radialis brevis will be cut, but that of the longior will escape for the present, and the angle formed by the two parts of the incision should be close to the inner side of its insertion. If the first part of the incision be carried

useful arm, of which the annexed figure is a good representation, was left (Fig. 556). After a time the hand gradually inclines towards the radial side of the arm; but, although the articulation between it and the forearm is but a slender one through the medium of the ulna, a very useful member will be left. These operations do not require any specific rules for their performance; the bone is exposed by a long incision in the direction of, and made by slitting up, the sinuses that burrow amongst the muscles, and is then carefully dissected out from the parts amongst which it lies; especial care being taken to preserve the periosteum and any new bony deposits that may already have been formed. In one case in which the elbow-joint was involved, and the radius diseased, instead of amputating the limb I obtained an excellent result by excision of the articulation as well as of the affected bone. The patient, a builder about thirty years of age, was able, four years after the operation, to use his hand not only for all the ordinary purposes of life, but also in his trade.

The **Olecranon** has been successfully removed in some instances; for disease by Birkett of Guy's Hospital; and on account of non-union after fracture by Newman of Stamford. In each case a useful arm was retained.

#### DISEASES OF THE WRIST-JOINT.

**Tuberculous disease** of the wrist is more common in adults than in children. Watson Cheyne believes that the disease is often primarily synovial and that when it commences as an osseous deposit, this is usually in the lower end of the radius or in the base of one of the metacarpal bones, especially the second and third. Although the disease rarely begins in the carpus, this is usually secondarily affected through its synovial cavities. It is an important fact that in tuberculous disease of the wrist the surrounding tendon sheaths may become extensively affected, whilst in other cases the primary disease seems to be a tuberculous teno-synovitis, the joint being involved secondarily. In some instances also the joint disease has followed chronic effusion into the sheath of the flexor tendons, the so-called "compound ganglion." In these cases the distended sheath has contained melon-seed bodies, a condition which is itself in all probability often tuberculous.

In cases of tuberculous disease of the wrist requiring operative interference excision has given good results in adults. In children, as we have seen, the disease is rare and should be treated as far as possible by partial operations. Amputation will sometimes be found necessary when the disease is very extensive or when recurrence has occurred after excision.

**Excision of the Wrist** formerly found less favour with Surgeons than the removal of other joints. The objections raised to it were, first, that in caries of the carpus the disease very often extends rapidly, with great constitutional disturbance, to all the small bones that enter into its formation, and consequently partial operations rarely succeeded in curing the disease; and secondly, that owing to the superficial character of the articulation, and its close connexion with the flexor and extensor tendons, methodical operations by the older methods were almost invariably followed by a stiff and useless hand. Further experience has, however, shown that complete excision of the carpus with the lower ends of the bones of the forearm, and the bases of the metacarpal bones, may in suitable cases be undertaken with a good prospect of preserving a useful hand. I had a case in 1858, in the person of a middle-aged

man in whom the whole carpus and a portion of the bases of the metacarpal bones were removed, and who recovered with a very useful hand, with some power of flexing and extending the wrist, and with very considerable mobility of the fingers. To Lister, and to West of Birmingham, however, is due the merit of proving the practicability of the operation. The mode of operating planned by the former of these Surgeons will be described here. But before giving the details of this operation, it may be well to mention the principles on which it is founded. On looking at the movements of the wrist-joint, it will be seen that they are somewhat limited in extent, so that if tolerably firm fibrous ankylosis can be obtained between the lower ends of the radius and ulna and the upper ends of the metacarpal bones, the normal amount of movement is maintained. Should these movements be lost or should the union be so loose as to necessitate the application of a rigid apparatus to support the wrist, the hand may still be perfectly useful, the lost movement of the wrist being supplemented by those of flexion and extension at the elbow. But the hand cannot be useful if the flexion and extension of the fingers be seriously interfered with. The essential principle of Lister's operation is to preserve uninjured all the tendons concerned in the movements of the thumb and fingers. If we look at the tendons that surround the wrist, we shall find them divisible into five groups: 1. Those special to the thumb; 2. The extensors of the fingers; 3. The flexors of the fingers; 4 and 5. The extensors and the flexors of the wrist. Now the incisions are so planned as to save the whole of the first three groups, and to divide only the tendons of the wrist proper, and these are cut so close to their insertions that as a rule they form new attachments and resume their functions as recovery takes place.

**Lister's Operation.**—From the result of two cases of severe injury to the wrist-joint, which recovered with useful hands, Lister was led to the conclusion that, with proper after-treatment, the tendons about the wrist might be very freely handled without permanent stiffness resulting. At the same time, he hoped by removing the whole of the cartilaginous surfaces to be able to prevent recurrence of the disease—which is the common ending of cases of partial excision of the wrist-joint for caries of the carpus. At the time when he published his papers, he had performed the operation of excision of the wrist fifteen times. The method of operating was essentially the same in all; various small details being altered as experience suggested. The operation, as he now performs it, is done as follows. Esmarch's bandage and tourniquet should be applied, as without them the oozing of blood interferes considerably with the operation. Any adhesions of the tendons then existing must be forcibly broken down by moving the joints. An incision is now made "from about the middle of the dorsal aspect of the radius, on a level with the styloid process, downwards and outwards towards the inner side of the metacarpo-phalangeal articulation of the thumb; but, on reaching the line of the radial border of the metacarpal bone of the index finger, it is carried downwards longitudinally for half the length of that bone." This incision should commence in the angle formed by the tendons of the common extensor of the fingers and the extensor longus pollicis, and the upper part should run parallel to the latter tendon, but without injuring it. The tendon of the extensor carpi radialis brevis will be cut, but that of the longior will escape for the present, and the angle formed by the two parts of the incision should be close to the inner side of its insertion. If the first part of the incision be carried

too far, there is danger of wounding the radial artery. The soft parts are then to be separated carefully from the bones on the radial side of the incision, the tendon of the extensor carpi radialis longior being now cut as close to its insertion as possible. The tendon of the extensor longus pollicis and the radial artery are to be pushed outwards out of the way. The trapezium must then be separated from the rest of the carpus by cutting in the longitudinal part of the incision with the bone-forceps. The soft parts on the ulnar side of the radial incision are now to be dissected up as far as can conveniently be done, the remainder being raised from the ulnar incision. While this is being done, the tendons must be relaxed by extending the joint. The trapezium is not to be removed yet, as any attempt to dissect it out before removing the rest of the carpus would endanger the radial artery and the tendon of the flexor carpi radialis. The ulnar incision is next to be made. It must be a free

incision, commencing at least two inches above the end of the ulna and immediately to the palmar aspect of the bone, and being carried directly downwards between the flexor carpi ulnaris and the ulna, and then straight on as far as the middle of the palmar aspect of the fifth metacarpal bone. The tendons and soft parts on the dorsum of the carpus are now to be completely raised. In doing this the tendons must be relaxed, and they are to be raised as little as possible from the radius or metacarpus. The extensor carpi ulnaris is to be cut as near its insertion as possible, and the dorsal and internal lateral ligaments may now be divided. Then the soft parts are to be raised from the palmar aspect. The knife must be carried close to the ulna, so as not to wound the artery and nerve. The pisiform bone is to be separated and left attached to the tendon of the flexor carpi ulnaris, which is not to be cut. The flexor tendons are to be raised from the metacarpal bones, but in doing this

the hook of the unciform bone must be clipped off with the bone-forceps, and care must be taken not to cut below the bases of the metacarpal bones, for fear of wounding the deep palmar arch. The tendons must be relaxed during this part of the operation by flexing the wrist. The bone-forceps may now be introduced, first between the carpus and radius, and then between the carpus and metacarpus; by this means the whole of the carpal bones (except the trapezium and the pisiform bone) are separated from their connexions, and may be extracted in one mass with a large pair of sequestrum-forceps, any bands which retain them being touched with the knife.

The ends of the radius and ulna may now easily be protruded from the ulnar wound. If on examination they be found only slightly diseased, the ulna may be sawn obliquely so as to remove only its articular surface and to leave almost the whole of the styloid process. A thin slice may be taken off the end of the radius, so as to remove only the cartilaginous surface; and its articular surface for the ulna may be cut away longitudinally with the bone-forceps or a chisel. By leaving the ulna as long as possible and by saving the styloid process, the tendency to displacement of the hand to the ulnar side is somewhat counteracted. If the bones be extensively diseased, the gouge and bone-pliers must be used freely. The next step is expose the bases of the metacarpal bones, and to treat them in the same way as the radius and ulna, saving as much bone as possible, but removing all cartilaginous surfaces with a narrow-bladed saw. The second and third are most easily protruded from the radial, and the fourth and fifth from the ulnar, wound. The trapezium may then be dissected out, being held in a strong pair of forceps. In doing this care must be taken, first, not to wound the radial artery, which is in close relation with its outer side; and, secondly, not to cut the tendon of the flexor carpi radialis, which lies in its groove. When the trapezium is removed, the base of the metacarpal bone of the thumb may be pushed up and cut off with the bone-forceps or a small saw. It is better to remove it, as it may suffer from recurrence of the disease, and by its removal the thumb is reduced in length to the same extent as the fingers. Lastly, the pisiform bone may be examined, and either removed entirely, or its cartilaginous surface cut off, as the case requires. During the operation, the only tendons necessarily divided are the extensors of the wrist. The flexor carpi radialis may escape, from its attachment being situated low on the bases of the second and third metacarpal bones, and the flexor ulnaris is left attached to the pisiform bone. All the extensors of the thumb should be uninjured. All the tendons necessarily divided must be cut as long as possible, so that they may form new attachments in the most advantageous positions; and, in raising the flexor and extensor tendons, they must be disturbed as little as possible.

**After-treatment.**—The radial wound may be closely united with sutures. The ulnar wound may be closed at each end, but the middle of the wound is to be kept open by means of an india-rubber drainage-tube to allow free exit of discharge. The hand is to be placed on a splint. The most convenient is a simple wooden splint, “with an obtuse-angled piece of thick cork” stuck on it so as to maintain the hand in a state of semi-flexion, with the wrist slightly extended (Fig. 560). The thumb is supported by a bar of cork stuck on the under surface so as to project at the side (Fig. 561). The two great objects in after-treatment are to get the fingers perfectly movable and the wrist firm. For these purposes passive motion must be commenced as early as the second

day in the fingers, each being bent and extended every day fully, while the wrist is kept firmly on the splint and disturbed as little as possible during the treatment of the fingers. Special care must be taken to flex the metacarpophalangeal articulations, which are very apt to remain stiff. Pronation and supination must not be too long neglected. Passive motion must be maintained as long as there is any tendency to the formation of adhesions in the sheaths of the tendons. As the hand becomes stronger, the part of the splint supporting the fingers may be cut off. The patient must continue to use some support as long as he feels any weakness in the wrist. There is often some tendency to dropping of the wrist to the ulnar side, which is best counteracted by a properly constructed gutta-percha splint. The thumb is apt to be drawn in towards the index finger; this must be prevented by a thick pad of lint kept from the earliest time between the two.

The essential points are, first, exact attention to all the details of the operation, and next, a careful and patiently conducted after-treatment.

Other methods of excising the wrist have been introduced by Ollier and

Fig. 500.—Lister's Splint with Cork Support for Hand.

Fig. 501.—Hand after Excision of Wrist, laid on Splint.

Langenbeck, the former by means of two dorsal incisions, the latter by a single dorsal incision along the outer border of the tendon of the extensor indicis.

**Results.**—Since Lister described his method of operating, excision of the wrist for disease has become a recognized operation of Surgery, and has been practised successfully by West (five cases), Gillespie, and many other Surgeons. In military surgery, however, according to the statistics of the American war, the results of the operation have been far from encouraging in regard to the amount of mobility left to the hand.

#### CONSERVATIVE SURGERY OF THE HAND.

In the removal of diseased or injured portions of the hand, it is, as a general rule, of the greatest importance to sacrifice as little as possible of the healthy or uninjured structures. In all operations on the hand, indeed, we must keep two great principles in view—the preservation of the utility of the member, and the maintenance, as far as practicable, of its symmetry. Utility is

necessarily the primary consideration ; but if a part be not useful, it may, as in the case of the head of the middle metacarpal bone in amputation of the corresponding finger, be sacrificed for the purpose of preserving the symmetry of the maimed limb. The hand is the organ of *prehension* and of *touch* ; and in all operations performed on it we should endeavour, as far as practicable, to preserve its efficiency in both these respects. It is also of importance to bear in mind that two great classes of actions can be carried out by the hand—those that require force, and those that require delicacy of manipulation rather than strength. By a surgical operation we may sometimes succeed in preserving one, though we are compelled to sacrifice the other. Thus, by partial excision, we may leave a hand that would enable a clerk to hold his pen, though it would be almost useless to a labourer or blacksmith.

We may consider the hand as being composed of two constituents—the hand proper, and the *Thumb* ; the thumb being an opponent to the rest of the member, without which its utility is comparatively limited. Hence, in all cases of injury or disease implicating the thumb, every effort ought to be made to preserve it. Even if it be left stiffened and incapable of flexion at the interphalangeal joint, it will be a most useful opponent to the rest of the hand. Should it be found necessary to shorten it, care must be taken that as little as possible is removed ; a portion of a phalanx, or its metacarpal bone even, is of essential utility in giving strength and breadth to the grasp of the hand. In cases of disease, a very useful member may be left by the removal of a portion or the whole of the ungual phalanx, of the metacarpo-phalangeal articulation, or even by the excision of the metacarpal bone, the phalanges being left. These various operations are easy of performance ; an incision through the diseased and disorganised soft parts will expose the necrosed bone or carious joint, which must be removed by cutting-pliers or a narrow saw.

When the thumb has been forced back, or badly lacerated by powder-blast or gun-barrel explosions, it may often be saved by being replaced and maintained in position on a splint, with some form of antiseptic dressing applied to it ; and, should amputation be required, it must be done in accordance with the rule just mentioned—of saving as much as possible of the injured part.

In the conservative surgery of the **Fingers** the preservation of flexion and extension in the part left is the main thing to be aimed at ; a rigid stump is always in the way. The preservation of these movements becomes more important in proportion as the palm is approached. It is of greater consequence that the proximal phalanx, which carries the rest with it, should be capable of being bent into the palm, than that the distal can be flexed on the second. If the proximal phalanx can be bent down, a very small degree of movement in the distal one will be sufficient to furnish pliability enough in the finger to make it a useful member ; but if the proximal one be stiffened, no amount of mobility in the distal phalanx can make it useful.

In preserving these movements, it is necessary to be particularly careful of the sheaths of the tendons. If these be opened or injured, it will generally be found either that the tendon sloughs, or that it becomes adherent to its sheath in such a way that movement is lost, or greatly impaired.

The only phalanx that can be excised with advantage is the distal one. It often happens, in the destructive disorganization which results from whitlow, that this necroses ; when, instead of amputating the end of the finger, it may

be removed by an incision on its palmar aspect. Disease of the phalangeal articulations usually leads to amputation of the affected finger. The rules for performing these various operations have already been laid down in Vol. I., pp. 93 *et seq.*, to which I must refer the reader.

Resection of the **Metacarpal Bone**, either of the thumb or index finger, without the removal of the corresponding digit, is occasionally required, more particularly in cases of injury; it may readily be done by making a longitudinal incision over the dorsal aspect of the bone to be removed, carefully detaching it from surrounding parts by keeping the edge of the knife close against the bone, avoiding the tendons, and then either disarticulating, or (what is preferable) cutting across the neck of the carpal end of the bone, turning it out, and separating it from any distal attachments which it may retain. After the removal of the metacarpal bone of the index finger in this way, but little deformity results, and a very useful hand will be left, more particularly in children, on whom I have more than once practised this partial resection with success. If the periosteum be saved, the bone may be to some extent reproduced, but in order to obtain this result it is necessary to keep the finger drawn forwards by an elastic extending apparatus, to prevent the first phalanx from being pulled back on to the carpus by the muscles attached to it.

**TUBERCULOUS DACTYLITIS.**—This affection, which is often spoken of as “strumous dactylitis” and constituted one condition termed *Spina ventosa* by the older writers, usually commences as a tuberculous osteomyelitis of a metacarpal bone or phalanx. It is very common in young children and several bones are often affected. It is characterized by a gradually increasing fusiform enlargement of the affected bone. The adjacent joints usually escape and in many cases spontaneous cure occurs with a shortened but useful finger. In the early stages the treatment should consist in attention to the general health and the administration of cod-liver oil; the affected finger should be fixed on a small splint. If a chronic abscess form this must be opened, and then by enlarging the track, which will usually be found leading into the expanded bone, the tuberculous granulation tissue and any existing sequestrum can be thoroughly scraped out. A lasting dressing should then be applied and in the majority of cases a good result will follow. Amputation is rarely necessary unless a joint is involved.

## CHAPTER L.

## DISEASES OF THE BONES AND JOINTS OF THE LOWER EXTREMITY.

In this chapter are considered the clinical features presented by the various affections of the important bones and articulations of the lower limb, and the different operative procedures required in their treatment. In the consideration of this subject it is essential to bear in mind that the object of all treatment must be to secure a good basis of support, of sufficient length and stability. The conservative operations performed differ thus in some important respects from those that are practised on the upper extremity. In the latter, the preservation of the hand, even though in a mutilated condition, is the object at which the Surgeon aims ; and, provided this be attained, it matters comparatively little how much the arm may be shortened or impaired in power. In the lower extremity, however, strength, length, and solidity are essential to the patient's comfort and utility, and unless these can be secured, his interests are better served by the removal of the limb, and the adaptation of some artificial contrivance, than by leaving a shortened, wasted, and crippled member, which is unable to support the weight of the body.

## DISEASE OF THE SACRO-ILIAC JOINT.

**Disease of the Sacro-iliac Joint** is a rare affection. Although it was mentioned by earlier writers, it is to Nélaton that we are indebted for the first detailed description of the disease. It has in many cases, no doubt, been confounded with some of the varieties of disease of the hip or spine. Makins finds that of 1622 cases of joint disease treated in St. Thomas's Hospital during the ten years 1881 to 1890, in only 13 was this joint affected, whilst the hip was diseased in 660. Barker found the same number of cases in a similar period at University College Hospital. The disease appears to be most commonly met with in young adults, and I have myself never seen it in young children. In Barker's thirteen cases the ages varied between 15 and 52, the average being 27 ; whilst of Makins's cases two were between 5 and 10, four between 10 and 20, four between 20 and 30, one between 30 and 40, and two between 40 and 50. The two sexes appear to be about equally affected : thus adding 57 cases collected by Poore of New York to those above mentioned we have a total of 83 cases—41 males and 42 females.

**Pathology.**—Acute destructive inflammation of the sacro-iliac joint is said to have occurred as the result of pyæmic infection, and it may follow the direct invasion of the joint by an abscess in the neighbourhood. An example of this form of disease occurred recently in University College Hospital. A woman died of pyæmia on the thirty-seventh day after parturition. At the *post-mortem* examination septic phlebitis of the vaginal veins and the internal

iliac vein was found on the right side, resulting from a small laceration of the upper part of the vaginal wall. In addition to this there was an abscess beneath the periosteum of the right iliac fossa, which had extended inwards to the hollow of the sacrum and into the right sacro-iliac joint, the cartilage of which was eroded.

In the chronic forms, with which we are here solely concerned, the disease

Fig. 562. — Sacrum.

Fig. 563. — Ilium.

is undoubtedly tuberculous in nature. It may commence primarily in the pelvic bones, in the articular structures of the sacro-iliac junction, or between the lateral epiphysial plate of the sacrum and the body of the bone, which do not unite till the twenty-fifth year. The annexed drawings (Figs. 562, 563), taken from a boy who died of tetanus from the irritation of an issue, six weeks after the commencement of disease in the sacro-iliac articulation, show erosion of the cartilages in patches. The next drawing (Fig. 564), taken from a man about 30 years of age, who died of this affection after nearly two years of suffering, shows the disease in its most advanced stage. The bones were bare and rough, but not necrosed; they were completely deprived of their incrusting cartilage. There was no deep erosion of them, no cavity, no sign of tuberculous infiltration; no evidence, in

fact, of primary osseous disease. The ligamentous structures of the articulations were only partially destroyed. The interosseous ligament especially was in a sound state; it had preserved to a great extent its firmness, and required to be divided with the scalpel in order to expose the interior of the joint and the opposed osseous surfaces. The structures that appeared chiefly to have suffered were the synovial and cartilaginous elements of the joint. The synovial membrane is normally but imperfectly developed in the sacro-iliac articulation, but it probably undergoes changes analogous to those which take place in the tuberculous disease of other joints.

Fig. 564. — Sacro-iliac disease, more advanced.

The **Symptoms** of sacro-iliac disease arrange themselves in five distinct groups—viz., Pain, Swelling, Lameness, Alteration in the Shape of the Limb, and Abscess. These we must study separately.

1. **Pain.**—One of the earliest symptoms is a sensation of painful weakness at the lower part of the back and sacrum, increased by movements of the body in walking, stooping, or even in standing, giving the sensation as if the body

were falling asunder. The pain is increased by any effort that calls the respiratory muscles into action, such as coughing, sneezing, or laughing, and is greatly aggravated by straining at stool. As the disease advances, the pain becomes more continuous, and of a gnawing or rheumatic character. Its intensity varies greatly: in some instances it is throughout slight, except on movement; in others it is excruciating, the patient shrieking with agony, and being unable to obtain rest in any position. The pain in the gluteal region may in some cases be due to irritation of the lumbo-sacral cord, which lies in close contact with the articulation. The pain is usually confined to the gluteal region and groin, but may extend down the thigh. When the patient is lying on his back or side, the limb on the affected side may be abducted or adducted, or the head of the thigh-bone may be pressed up against the acetabulum, without any increase of pain, provided the pelvis be fixed by the pressure of the hands. If this be not done, considerable, even intolerable, pain will be experienced on moving the limb. So, also, if the Surgeon seize the sides of the pelvis in his hands, and move them to and fro, or press them together transversely, or separate them by pressing the anterior superior spines asunder, pain will be elicited, the affected joint being then influenced by the movement. There is often diffused tenderness on pressure over the gluteal region; but this is less about the hip-joint than in coxalgia, and gradually increases as the finger is pressed backwards upon the sacro-iliac articulation, so that it may at last be localized in a small spot.

2. **Swelling.**—A puffy swelling may be perceptible early in the disease, over the affected articulation. It assumes a somewhat elongated appearance from above downwards, and does not extend to any distance outwards under the gluteal muscles, nor does it invade the natural hollow behind the trochanter. As the disease advances, and suppuration takes place, the swelling increases materially, and assumes different and peculiar characters.

3. **Lameness** is an early symptom. The patient walks insecurely; has a feeling of want of proper support to the body; leans forward, and uses a stick. He puts the foot of the affected side to the ground, but does not tread upon it so firmly as upon the other; he cannot stand on it, or twist himself suddenly round. As the disease advances, the powers of support and progression diminish, and at last the patient becomes unable to assume the erect position, lying in bed usually on the sound side.

4. **Alterations in the Shape of the Hip and Length of the Limb** are early and marked symptoms. From the very commencement of the disease, the limb on the affected side will seem to be longer than the sound one; the tip of the inner malleolus being usually, as the patient lies on his back, half an inch below the level of the same point of bone on the opposite side. But on close examination, it will be found that the measurement from the anterior superior spine to the inner malleolus gives the same result on both sides: hence the elongation cannot be owing to any change that has taken place in the bones or in the three large joints of the lower extremity, but must be dependent on some disturbing cause situated beyond the anterior superior spine of the ilium. On closer investigation, this point of bone is found to be at a lower level, and at the same time more prominent, than its fellow on the opposite side: the displacement is thus produced, not by any obliquity of the pelvis consequent on a twist of the lumbar spine, as in hip-joint disease, but by the tilting forwards and rotation downwards of the whole side of the

pelvis. The swelling of the affected articulation not only pushes forwards, but rotates downwards, the anterior and superior portion of the ilium; and hence the anterior superior spine is not only at a lower level, but is also more prominent on the diseased than on the sound side. The limb itself usually lies straight, and is wasted and enfeebled.

5. **Abscess** occurs only at a late period of the disease. Many months, a year or more, may elapse before suppuration is fairly established, or, at all events, before the formation of pus is so abundant that it can be recognized as an abscess. I have observed abscess in connexion with this disease in five situations—viz., over the articulation, in the gluteal and in the lumbar regions, within the pelvis, and in connexion with the rectum.

The first indication of abscess is met with over the diseased articulation. The puffy swelling, which is there perceptible in the earlier stages of the affection, gradually softens, until at last fluctuation is established in it. From this point it may spread outwards into the gluteal region, nearly as far as, but not enveloping, the trochanter; or it may take another course and stretch upwards, forming a considerable accumulation in the loin, upon and just above the crest of the ilium. These forms of sacro-iliac abscess are *extrapelvic*; the other varieties are *intrapelvic*. The latter are of three kinds. In one form the pus passes out of the sciatic notch, and under the great gluteal muscle; in the next it gravitates downwards into the ischio-rectal fossa, and presents by the side of the rectum; and in the third variety which I have observed, the abscess opens into the gut, abundant discharge takes place *per anum*, and, flatus from the bowel passing into the suppurating cavity, a tympanitic abscess results.

The **Diagnosis** of sacro-iliac disease is important, and not always easy. There are five distinct affections with which it may be confounded—viz. neuralgia of the hip, sciatica, spinal disease, disease of the hip-joint, and disease of the pelvic bones.

1. *Neuralgia of the hip* in young females may readily enough be confounded with the earlier stages of sacro-iliac disease. But the widely spread and superficial nature of the pain which is not limited to the neighbourhood of the diseased articulation, the co-existence of the hysterical temperament, and the sex of the patient render the true nature of the affection sufficiently clear. The obliquity of the pelvis which occasionally occurs in neuralgia of the hip, and causes apparent elongation of the limb, is readily removed when the patient lies on the back; whereas, in sacro-iliac disease, position does not affect the displacement of the limb on the affected side.

2. *Sciatica*.—In this affection, the age of the patient, usually more advanced than that of the subjects of sacro-iliac disease; the seat of the pain, below the articulation, and its extent down the back of the limb, the tenderness being in the line of the great sciatic nerve, and not over the articulation, and the fact that it is not increased by pressing on the iliac spines; with the absence of deformity, will enable the Surgeon to make the diagnosis.

3. From *spinal disease*, the diagnosis is usually sufficiently easy: for although the situation of an abscess arising from caries of the vertebræ may be the same as of that which results from sacro-iliac disease, yet in the vast majority of cases of caries of the spine, excurvation of the vertebræ has become prominently marked by the time that the abscess has acquired so large a size as to occupy the inferior lumbar or gluteal regions. In some

instances, however, an extensive abscess may form without any alteration of the normal outline of the spine, whilst caries affecting the hollow of the sacrum may lead to the formation of an intrapelvic abscess exactly agreeing in situation with those due to sacro-iliac disease. In the case of disease of the sacrum the presence of the abscess may be the only symptom; and whereas in lumbar caries there will generally be found more or less fixation of the part with perhaps tenderness on percussion over the affected region, yet these signs also may be absent. Under these circumstances the exclusion of sacro-iliac disease will depend upon the absence of the characteristic symptoms of this affection—pain, swelling over the joint, and displacement of the side of the pelvis with elongation of the limb on the affected side.

4. *Disease of the hip-joint* is the affection most easily confounded with sacro-iliac disease, and that from which it is of most importance to distinguish it. It is especially from that variety of hip-disease which commences in the acetabulum, primarily involves the pelvic bones, and only secondarily implicates the joint, that it is difficult to distinguish sacro-iliac disease; and the importance of recognising the nature of the case is great when we reflect that an error in diagnosis might lead to the performance of an unnecessary operation on the hip-joint. The diagnosis may be made by attention to the following circumstances:—

a. The seat of pain on pressure varies. In hip disease the patient suffers severely when pressure is made deeply in the hollow behind and above the trochanter, or against the anterior part of the hip-joint. In sacro-iliac disease, little or no pain is experienced on pressure in these situations; but tenderness is elicited by pressing upon the sacrum and along the line of junction between that bone and the ilium, behind and altogether away from the hip.

b. The movements that occasion pain are different in the two diseases. In hip disease, abduction and rotation outwards, and pressure of the head of the thigh-bone into the acetabulum, aggravate the sufferings of the patient. In sacro-iliac disease the thigh may be moved in all directions, abducted or adducted, rotated, flexed, or extended, whilst the patient is lying on his back, without any increase of suffering, provided the side of the pelvis be fixed by the Surgeon. Should this precaution not be taken, the movement impressed on the thigh will be communicated to the diseased articulation, and will necessarily cause pain.

c. The signs connected with the alteration in the length of the limb differ in the two diseases. In hip disease there may be, and usually is in the advanced stages, considerable shortening. This never occurs in sacro-iliac disease.

d. The alteration of the level, and of the prominence of the two anterior superior spines, in sacro-iliac disease, may be confounded with that arising from the obliquity of the pelvis usually occurring in the early stages of coxalgia. But here also the diagnosis may be made by observing that the displacement of the bone in sacro-iliac disease is permanent, and is not influenced by position. The obliquity of the pelvis in hip disease, giving rise to apparent elongation of the limb, is dependent on a twist in the lumbar spine, which may be rectified by placing the patient on his back, and using a little manipulation. The alteration in the level of the two ilia, in sacro-iliac disease, is not modified by change of position, or by any movement that may be impressed upon the spine.

5. *Disease of the pelvic bones* may of course occur independently of any affection of the sacro-iliac articulation ; and, when so occurring, it most commonly commences at a distance from the joint—the crest of the ilium, the tuberosity of the ischium, or the acetabulum, being the usual seats of the disease. When it occurs in the first of these two situations, the resulting abscess seldom attains a very large size, and is altogether above or below the articulation, the outline of which can be clearly felt and is unobscured by swelling. When the abscesses are opened, the sinuses that result will lead directly down to the rough and carious bone, examination of which will leave no doubt as to the nature of the case. In these cases, also, no change takes place in the length of the limb, or in the position of the side of the ilium.

When the acetabulum is affected, the difficulty of diagnosis may be greater, in consequence of the large size and often intrapelvic nature of the abscesses. But here the same circumstances that enable the Surgeon to make a diagnosis in ordinary hip disease—viz., the pain in movement influencing the hip-joint merely, and the alteration in length of limb, as determined on measuring from the anterior superior spines—will prevent his falling into error as to the true nature of this disease.

In doubtful cases of intrapelvic abscess rectal examination may be useful.

The **Prognosis** of sacro-iliac disease is more unfavourable than that of tuberculous joint affections in general, and this can no doubt partly be accounted for by the fact that it tends to occur in adults, and further that the anatomical relations of the joint render thorough operative treatment difficult. The more favourable prognosis when the disease occurs in children is doubtless partly due, as Makins suggests, to the light weight of the trunk. Of recent years considerable success has followed the treatment of sacro-iliac disease upon the same principles as are applied to tuberculous joint disease elsewhere. The prognosis is necessarily much better if the formation of an abscess can be avoided. I have seen a case cured, in which, from the history of the symptoms, the thickening over the sacro-iliac articulations, and the permanent displacement of the side of the pelvis, there was every reason to believe that this disease had existed.

The **Treatment** must as far as possible be conducted on the same general principles as are adopted in tuberculous diseases of other joints. In the early stages complete rest is essential, and if a cure be fortunately accomplished, the patient will probably recover with a limb that, though weakened, is but little impaired in utility ; for the sacro-iliac junction being naturally a fixed joint, it matters little if, in the adult, it become ankylosed by disease. Long continued rest in the prone position ; fixing the pelvis, hip-joint, and thigh by means of a large leather cap and splint, or a plaster of Paris bandage, which should embrace the whole of the limb from above the crest of the ilium to the sole of the foot ; counter-irritation ; the administration of cod-liver oil, iron, and suitable tonics, are the means to be employed. In children a double Thomas's splint should be applied to which the pelvis may be fixed by a plaster of Paris bandage.

If an abscess forms this must be freely opened and the cavity thoroughly scraped and flushed. The edges of the incision being held apart, careful search must be made with a probe for a track leading towards the joint. If this enter it directly on the inner side of the posterior superior iliac spine the track should be enlarged and the articulation thoroughly scraped, special

attention being given to any pits on the articular surfaces which may contain soft carious bone or sequestra. In some cases the track leading to the joint will be found to pass over the iliac crest or through the great sciatic notch. Under these circumstances the seat of disease can best be reached, and any intrapelvic collection of pus drained, by trephining the ilium over the position of the joint, as has been practised by Golding-Bird, Mayo Collier, Makins, and others. In Golding-Bird's case a psoas abscess connected with the front of the joint was drained and the patient made a good recovery. In Makins's case "a three-quarter inch trephine was applied one and a half inches before and below the posterior superior spine;" the joint was scraped and the resulting sinus slowly healed. In some cases the Surgeon may completely close the wound, but if the disease is extensive he will be wise to insert a drainage tube. Every care must be taken to prevent decomposition, for the fatal result, which was at one time almost inevitable in these cases, often ensued from hectic and albumenoid disease due to an imperfectly drained and septic intrapelvic abscess.

#### DISEASE OF THE PELVIC BONES.

This most commonly occurs in association with disease of the hip-joint or more rarely of the sacro-iliac articulation, and is considered with those affections. It occasionally happens, however, that necrosis of some part of the pelvis may result from acute suppuration beneath the periosteum, or from the breaking down of a subperiosteal gumma, whilst tuberculous caries sometimes occurs independently of joint disease. Necrosis is especially apt to occur in the crest of the ilium or in the ischial tuberosity. The sequestra may be extremely slow in separation, and excision of considerable portions of the pelvis has been successfully practised in such cases.

Caries of the ilium may lead to complete perforation and the formation of an abscess on both surfaces of the bone. Under these circumstances the abscess on the dorsum ilii should be freely opened, and by scraping away the soft carious bone efficient drainage may be established for the abscess within.

#### DISEASE OF THE HIP-JOINT.

No subject in the whole range of practical Surgery has received more careful attention than that of the various diseases of the hip-joint. This is readily understood when we consider the many variations presented by the different affections; the great difficulty which is often encountered in making an accurate diagnosis; the serious danger to the utility of the limb, if not to the life of the patient; and the many important questions which arise in connexion with the treatment of diseases of the hip-joint. It is, however, very necessary that the Surgeon should bear in mind that the affections of this joint are pathologically the same as those of other articulations, and that the same principles must guide him in their treatment.

The terms "**Hip Disease**" and "**Morbus Coxæ**," used in their broadest sense, have no pathological significance, whilst any painful affection of the hip-joint may justly be called "**Coxalgia**." It has, however, become customary to apply these terms more or less exclusively to the chronic diseases of the joint which are tuberculous in nature. To avoid confusion it is desirable

that these general expressions should, as far as possible, be avoided, and the different affections accurately named according to their pathology.

**SYNOVITIS OF THE HIP** may occur as the result of injury or may be rheumatic in nature. It is, however, not common, and derives its chief importance from the difficulty in some cases of distinguishing it from the earliest stages of tuberculous disease. The thick covering of muscles which surrounds the hip-joint renders the detection of slight effusion into it impossible, and thus the diagnosis of acute synovitis will usually be based upon the muscular fixation of the joint and the pain caused by the slightest movement. The position assumed by the limb is the same as that to be described subsequently in early tuberculous disease. In the consideration of the subject of spontaneous dislocations (Vol. I., p. 704), reference has been made to cases in which acute synovitis of the hip occurring in the course of an attack of acute rheumatism or typhoid fever, has caused such extreme distension of the joint as to lead to dislocation of the head of the femur. Rheumatoid Arthritis of the Hip has already been considered at p. 354, whilst Charcot's disease as it occurs in this joint requires no special description.

**ACUTE ARTHRITIS OF THE HIP.**—Acute destructive inflammation may occur in the hip in any of the forms which have already been described (see p. 336 *et seq.*). Thus we meet with an infective form, which may occur in cases of pyæmia, and with which must be included that sometimes resulting from puerperal fever, gonorrhœa, or one of the acute specific diseases, such as typhoid fever. Acute suppuration in the hip may result from acute necrosis of the upper end of the femur. When it is remembered that the epiphysal line between the head and the neck of the bone is altogether within the line of attachment of the capsule, it is easy to understand that suppuration commencing in this position will readily infect the joint cavity. In a case of acute suppuration in the hip recently in University College Hospital which proved fatal from pericarditis, it was found *post mortem* that the periosteum was stripped from a considerable part of the neck of the femur within the joint. There seemed little doubt that in this instance the primary affection was acute infective periostitis, the pus having burst through the periosteum into the cavity of the joint. In rare instances destruction of the hip-joint may result from the extension of suppuration into it from without, whilst cases are occasionally met with in which acute suppuration in this joint follows exposure to cold—the so-called “rheumatic arthritis” which has been described at p. 337.

The **Symptoms** of acute arthritis of the hip vary considerably in their severity and in the suddenness of their onset. The most acute symptoms are observed in cases in which the joint is affected secondarily to suppuration in the upper end of the femur. The patient is more or less suddenly seized with severe pain in the joint, accompanied by great constitutional disturbance and pyrexia. The pain in the joint is excruciating, accompanied by spasms and twitchings of the limb, and marked by nocturnal exacerbations. The suffering is so intense that the patient cannot bear the slightest movement of the limb; a fit of coughing, the weight of the bed-clothes, or the shaking of the bed by a person leaning against it will give rise to intense agony; and in the intervals of his suffering the patient is in constant fear of a return of the pain. In these cases the limb is flexed, everted, abducted, perfectly

helpless, and motionless; the nates will be found flattened, and there is usually some fulness about the anterior part of the joint, or to its outer side, in the hollow behind the trochanter. There is also theoretically true elongation of the limb, in consequence of the capsule becoming distended with fluid, and pushing the head of the bone downwards, but this seldom, if ever, occurs to such an extent as to be recognizable by measurement. On measuring in order to ascertain the true length, it is necessary to examine the two limbs together, and to place the sound in exactly the same position as the diseased one; unless this be done, error will very probably creep in. for, on measuring the lower extremity from the anterior superior iliac spine to the lower border of the patella or the inner ankle,

Fig. 565.—Acute Arthritis of Hip-joint in an Adult. Destruction of Head of Femur. Softening of Ligaments. Dislocation on to the Dorsum Ilii.

it will be found to be of greater length when abducted or extended than when adducted or bent.

In some cases the distension of the capsule with synovial fluid, as the result of the inflammation in the joint, may be so great as to lead to its rupture, and to the sudden dislocation of the head of the bone on to the dorsum ilii, with great pain and much shortening; this, however, is of very rare occurrence, the dislocation seldom taking place until after abscess has formed within the joint, and the articulation has been thus destroyed (Fig. 565).

The **Result** of acute arthritis of the hip depends greatly upon the constitution of the patient, the cause of the inflammation, and the manner in which it is treated. In the most favourable circumstances, as the inflammation subsides, the disease falls into the subacute condition, and recovery gradually but very slowly takes place, with a limb that continues stiff and partially

ankylosed, as well as wasted and somewhat shortened from disuse. Sometimes complete ankylosis occurs without the previous formation of abscess. In the majority of cases, however, suppuration occurs, and in many forms of acute arthritis, such as that due to acute necrosis of the upper end of the femur, it is inevitable in spite of all treatment. The pus soon escapes from the capsule, usually at its thin posterior part. When this occurs the acuteness of the symptoms often diminishes, and the abscess slowly burrows forwards and points near the tensor vaginae femoris. After it is opened, if decomposition of the discharges is not prevented, the patient may be worn out by the profuseness of the discharge; or great shortening taking place, either by the destruction or separation of the head of the bone or its dislocation out of the acetabulum, the cavity of the abscess may ultimately contract, the sequestra, if any are present, may exfoliate, the carious surfaces heal, and the sinuses close after years of suffering. In the most favourable circumstances, when once the joint has been acutely inflamed, a year or perhaps two will elapse before the patient can use his limb with any degree of security. It is needless to say that the infective forms of acute arthritis almost invariably end fatally.

The **Treatment** of acute arthritis of the hip joint in its early stages should consist in putting the joint at *perfect rest*. The great importance of preventing, as far as possible, all movement of the inflamed joint, has been considered at p. 340, and the means by which this is best secured in the case of the hip are described at p. 426. In this way suppuration may in some instances be avoided.

When once *suppuration has taken place*, the sooner the pus is evacuated the better. The retention of pus in the joint leads only to further disorganization of the articular structures, to continued constitutional irritation, and at length to bursting of the capsule, and the formation of large extra-articular abscesses. To Annandale we are indebted for having put this practice to the test of experience; by making a free incision into the posterior part of the joint, in conjunction with antiseptics and good drainage, he obtained the most satisfactory results.

Should the condition assume a chronic form with persistent discharge, and gradually increasing destruction of the bones, excision may be necessary.

#### TUBERCULOUS DISEASE OF THE HIP.

Tuberculous disease is by far the most common affection of the hip which comes under the care of the Surgeon, and includes the large majority of cases of subacute and chronic hip-disease occurring in early life. It is the affection to which the terms "Hip Disease" and "Coxalgia" are usually applied. The assertion that the disease now under consideration is tuberculous in nature rests upon the same evidence as that which has already been discussed in the consideration of tuberculous joint diseases in general (p. 343).

Tuberculous disease of the hip is most commonly met with before the age of puberty. Out of 48 consecutive cases of which I took notes, I find that in 16 only did it commence at or after fifteen years of age, and, of these, in 6 cases only it happened above twenty. The collected statistics of cases appear to give a very similar proportion.

The disease is commonly attributed to slight causes, such as over-exertion in a long walk, a sprain in jumping, a fall, or sitting in the wet. So frequent,

indeed, is the history of injury that traumatism was at one time looked upon as a most potent cause of chronic hip disease. At the present day, however, the simple traumatic inflammation is regarded rather as a local predisposing cause of the tuberculous disease.

**Pathology.**—It is very rarely that the opportunity occurs of examining a hip-joint in the early stages of tuberculous disease. By the time the patient dies or where excision is performed, the ligaments are swollen and softened, the synovial membrane is represented by a pulpy mass of granulation tissue, the cartilages have more or less completely disappeared, and the denuded osseous surfaces both of the acetabulum and femur are in a state of caries, so that it is impossible to determine with certainty the exact starting-point of the disease.

The following appearances found in a child about eight years old, who died in University College Hospital of pneumonia, and whose body was carefully examined by Wilson Fox, is a good example of the early conditions met with in tuberculous arthritis of the hip. The symptoms of hip disease had existed only about six weeks.

The joint, which was removed entire, contained a considerable quantity of dirty yellow pus. The ligamentum teres was flattened and covered with spots of yellow lymph; it was much softened, tearing with the greatest ease. The synovial membrane was generally greatly thickened, intensely injected, of colour varying from bright red to dull orange, and covered with spots of yellow lymph. The cartilage lining the acetabulum appeared to be healthy, except just around the insertion of the ligamentum teres, where it was softer and more gelatinous-looking than normal for about one to two lines. The cartilage covering the head of the femur appeared at first sight to be entirely unaffected.

On making a vertical section through the acetabulum, and the head and neck of the femur, the great trochanter was found to be unossified, with the exception of a point in its centre, and its connexion to the bone was weak and easily torn asunder. The epiphysis of the head was almost completely ossified; the line of junction being still, however, marked by a band of bluish and very hard cartilage, which extended for about three lines on each side across the bone. In the centre of this, extending both into the epiphysis and the diaphysis, was an eburnated portion of bone, yellow, hard, dense, and compact, these peculiarities being most marked in the portion belonging to the diaphysis. The cancellous spaces of this portion seemed to have been infiltrated with tubercle which had subsequently undergone calcification. In most parts this mass contrasted strongly in colour and in consistence with the reddened cancellous tissue. The articular cartilage, though generally appearing healthy superficially, could now be seen to be a good deal worm-eaten on its deep surface, and indeed, destroyed at one or two points. Where the mass of hard bone came near the surface, the reflexion of the synovial membrane was destroyed. Below this, in the neck and the upper part of the shaft, the cancellous tissue was very lax, the walls being very thin, and the medulla filling them extraordinarily red. The medulla at the commencement of the medullary canal, about one inch and a half below the trochanter, was exceedingly red and vascular. Occupying many spots of the cancellous tissue, and also one or two of the reddened medulla, were many little masses of the size of millet-seeds, looking like transparent cartilage, hard and resisting,

yielding no juice, not breaking down at all easily under the finger, torn with difficulty by the needle, and when torn showing great numbers of nuclei and fibres. They pervaded the whole bone, and were found also in the acetabulum, but in smaller numbers. Some of them could easily be enucleated where the medulla was soft: others could be separated only with difficulty from the cancellous bone.

In this case the disease evidently began in the upper end of the femur and secondarily involved the synovial membrane; it illustrates probably the most common form of the tuberculous affections of the hip.

According to the seat of the primary deposit, tuberculous disease of the hip may be divided into the synovial, acetabular, and femoral varieties, of which the last is probably the most common. It is generally agreed by writers on the subject that primary osseous deposits are more common than primary disease of the synovial membrane. Thus, of 132 cases of excision examined by Habernern, 80 were osseous, 23 synovial, and 29 doubtful. Watson Cheyne, who believes that synovial disease is less common in the hip than in the knee, does not think that the difference is so great as Habernern's figures would seem to indicate. The exact position of the primary tuberculous deposit in the upper end of the femur varies considerably: thus it may be found in the neck of the bone, in the great trochanter, or in the cancellous tissue of the head. Cheyne thinks that the usual position is the lower part of the neck just outside the epiphysal cartilage. When the disease commences in the acetabulum the deposit is usually situated near the Y-shaped cartilage, which is often rapidly destroyed. Acetabular disease is especially common in adults. In some cases, even at an early stage of the disease, tuberculous deposits may be found in both the acetabulum and femur. This was well illustrated in a case reported by Godlee, in which the disease was apparently receiving great benefit from treatment, when the child died of tuberculous meningitis. The examination of the hip showed two small tuberculous centres, each forming a cavity about the size of a pea, filled with soft granulation tissue. One was situated in the growing bone in contact with the Y-shaped cartilage of the acetabulum, and the other in the same tissue between the epiphysis of the head and the neck of the femur. The synovial membrane was injected, and its fringes swollen and becoming converted into granulation tissue.

It is unnecessary to describe in detail the various changes which the joint undergoes in the different varieties of tuberculous disease, for these have already been sufficiently discussed in a previous chapter. Certain points, however, are deserving of special consideration.

In cases of synovial disease, as soon as the cartilage covering the head of the femur has been destroyed, the cancellous tissue of the head which is already softened by rarefying osteitis may be rapidly worn away. When the upper end of the femur is primarily affected, sequestra are often present which may be soft and spongy, or of the dense wedge-shaped variety. In some cases the remains of the head of the bone may be completely separated as a sequestrum. In rare instances the disease may extend down into the upper part of the shaft as a tuberculous osteomyelitis. Slow destruction of the head of the femur may occur by a process of dry caries. One of the most important results of acetabular disease is complete perforation of the bone and the formation of an intrapelvic abscess. Sequestra are not uncommonly present in the acetabulum. The brim of the cotyloid cavity suffers most at its upper

and posterior part, against which the femur chiefly presses. Here the bone is worn away, and the conditions are rendered favourable for the occurrence of dislocation. The latter is usually a slow process, and as the head of the thigh-bone is gradually displaced upwards and backwards new bone is thrown out around it, and the acetabulum is correspondingly enlarged — the “wandering” acetabulum of German writers. In advanced cases extensive caries and necrosis of the neighbouring parts of the pelvis may result.

The changes in the synovial membrane need no special description. The round ligament of the joint is often destroyed at an early stage.

**Symptoms.**—In considering the symptoms of tuberculous disease of the hip-joint, it will be convenient to discuss briefly the following conditions:—Pain, Attitude, Imperfect Mobility, Suppuration, Sinuses, Dislocation, and Ankylosis. A short sketch of the clinical course of the disease will then be given.

1. **Pain.**—This is a more or less constant symptom but varies much in its characters and position. It may be referred to the region of the hip, but may extend down the limb, and not uncommonly is complained of only in the knee. This pain in the knee may be explained by the irritation of the articular branch of the obturator nerve, causing a referred pain to be felt in the terminal branches at the inner side of the knee-joint. Both the hip and knee also receive articular branches from the anterior crural and sciatic nerves. That from the obturator, however, enters the round ligament, and is perhaps for this reason implicated early in cases in which the disease commences in the head of the femur.

The pain is often associated with tenderness on pressure over the front of the joint or in the hollow behind the great trochanter. The character of the pain in the early stages is rarely of any value as an indication of the probable exact seat of the disease. Barker has, however, pointed out that in synovial disease the slightest movement of the joint causes much suffering, whereas if the disease be still limited to the femur or acetabulum, movement may be painless, whilst pressure on the trochanter or in the long axis of the limb at once causes pain.

Amongst the most distressing symptoms of some cases of hip disease are the painful startings of the limb which occur at night. These occur at the moment when the contracted muscles which fix the joint become more or less suddenly relaxed and movement of the inflamed surfaces on one another results. Starting pains are most severe when the articular cartilages are eroded, but they cannot be looked upon as a proof that this has occurred, for they are sometimes a marked symptom in the early stages of the disease, and are liable to occur in any case in which there is sufficient pain on movement to evoke involuntary muscular fixation of the joint.

2. The **Attitude** of the limb is peculiar, and varies during the course of the disease. In the early stages the limb is usually slightly flexed, abducted and rotated outwards, or in other words assumes the position of natural rest. The cause of this position has been the subject of much discussion. It has been proved experimentally by Bonnet and others, that the limb can be made to assume this attitude by forcibly injecting fluid, so as tightly to distend the capsule. The accompanying figure well shows this fact. It is from a photograph kindly furnished me by Barker, of a preparation made by himself. The right hip-joint was forcibly distended with fluid injected through a hole drilled into it through the ilio-pectineal eminence. That the limb may there-

fore assume the position from distension of the capsule by effusion from the synovial membrane cannot be doubted ; but in the great majority of cases of hip disease there is no reason to believe that any such distension takes place. That the position is not merely mechanical is shown moreover by the fact that in the early stages of the disease it usually disappears under chloroform. It may, however, be assumed that the position taken by the limb when all the ligaments are tensely stretched by injecting the joint, is also that in which there would be the most perfect general relaxation if the fluid were let out ; this position would therefore be assumed involuntarily by the patient when the

Fig. 1566.—Position assumed by the limb on forcibly distending the capsule of the right hip-joint with fluid.

capsule is inflamed. It has also been pointed out by Barker that in full extension "the leverage of the femur acting on the Y-ligament, and the tense anterior part of the capsule as a fulcrum," will force the head of the femur against the acetabulum, and for this reason the patient involuntarily keeps the thigh slightly flexed.

Hilton attributed the position of the limb to a reflex contraction of the muscles surrounding the joint, consequent upon the anatomical distribution of the nerves, it being a rule in all joints that they receive branches from the same nerves that supply the muscles acting directly upon them. According to this view the flexion, abduction, and rotation outwards are due to the stronger muscles prevailing over the weaker. It has been suggested also that the position may be due to the direct irritation of the flexors and external rotators which lie more immediately in contact with the capsule than the extensors and internal rotators.

When the limb is abducted, if the patient be put in the erect position, the pelvis is tilted in such a way that the anterior superior iliac spine of the diseased side will be found to be somewhat lower than its fellow ; at the same time the sound limb is adducted to a degree corresponding to the abduction of the affected side, and thus the two limbs are brought parallel to each other. The knee is flexed, partly on account of the lowering of the side of the pelvis and the flexion of the hip-joint, and partly because by putting the toes only to the ground, the elasticity of the foot is brought into play, and the pain prevented that would arise from the jar of the limb if the patient trod on the heel. The position assumed by the affected limb gives rise to an apparent elongation. Often in these cases of apparent lengthening there is actual shortening, but measurement from the anterior superior spinous process to the inner malleolus on each side shows the fallacy of this appearance.

As the disease advances, the position of the limb undergoes a complete change ; the flexion remains and is increased, but at the same time the thigh becomes adducted and rotated inwards, so that the knee is carried against the lower part of the sound thigh. The cause of this position has been the

subject of as much difference of opinion as that of the earlier displacement. In some cases it is undoubtedly due to destruction of the head of the bone and partial or complete dislocation. In these cases it is accompanied by distinct shortening with displacement of the trochanter above Nélaton's line. (Vol. I., p. 610.) Much more commonly, however, it sets in long before there are any signs of extensive destruction of the head of the bone, and must then arise from other causes. Busch has suggested that it may be due to the erosion of the upper and posterior wall of the acetabulum, so constantly met with as one of the earliest destructive processes in hip disease. In consequence of this the head is displaced upwards and backwards, so slightly at first as not to give rise to signs of dislocation, but enough, when the ilio-femoral ligament is unsoftened, to cause adduction of the limb. The altered position of the limb has also been ascribed to softening and yielding of the thinnest part of the capsule, the posterior and outer, while the inner and anterior part, which is much stronger, retains its toughness; to the external rotators becoming implicated early in the disease, as they lie most closely in contact with the capsule, and thus ceasing to oppose the adductors and internal rotators; and lastly, to the position assumed in bed by the patient when the diseased hip becomes too tender to bear any pressure. Probably all these causes are more or less concerned in the production of the adducted position, each acting in a different degree according to the circumstances of the case.

When adduction sets in, the position of the pelvis undergoes a change. In order to bring the limbs parallel and in a straight line with the body, the patient must now raise the pelvis on the affected side and abduct the sound limb, thus giving rise to apparent shortening of the limb on the side of the disease. This may occur without any or with very slight real shortening, the amount of which can be ascertained only by measurement.

The displacements of the pelvis and limb are accompanied by corresponding changes in the position of the spine. Owing to the tilting of the pelvis, there is a lateral curve produced in the lumbar region, the concavity of which looks towards the elevated side of the pelvis, and in order to keep the body straight, there is a compensating curve in the opposite direction higher up. At the same time the fixed flexion of the thigh is compensated for by an antero-posterior curvature of the lower spine with the concavity forwards, or as it is termed *lordosis*. This conceals the flexion of the hip-joint, so that the two limbs may lie side by side in bed apparently straight, when in reality the diseased hip is flexed to a considerable angle. When the limbs are in this position, if the hand be passed under the lumbar spine, it will be found to be arched forwards, not touching the bed. In order to estimate the amount of flexion, the plan recommended by H. O. Thomas is the best. As the patient lies on his back, the sound limb should be flexed to the full extent at the hip and knee, and pressed upon firmly till the lumbar spine becomes straight, and the hand can no longer be passed between it and the bed; the thigh of the affected limb will then be raised from the bed, and the true angle of flexion becomes apparent. The degree of adduction or abduction is best recognized by putting a tape across from one anterior superior spine to the other, when the angles formed by the limbs with this line are at once clearly seen.

The alterations in *length* are recognized by measurement from the anterior superior spine to the inner condyle of the femur or the inner malleolus, the limbs being placed as accurately as possible in the same position on the two

sides. If greater accuracy is required, the plan described in the chapter on Fractures (Vol. I., p. 611) may be adopted. Theoretically real lengthening may occur in consequence of effusion into the joint, but practically the amount so caused is too small to be recognized by measurement. True shortening may arise from destruction of the head of the bone, dislocation, and want of growth. In old cases it is well to measure the tibia separately, and to compare it with the sound limb. In this way the proportion of shortening due to general want of growth of the limb may be estimated roughly.

3. **Limitation of movement** is a constant symptom in all forms of hip disease. The degree of limitation of flexion is ascertained by grasping the side of the pelvis with one hand, while the thigh is slowly raised from the bed with the other. In this way it is easily ascertained how much of the apparent flexion is due to movement of the pelvis and lumbar spine, and how much to true movement in the joint. The degree of possible extension is recognized by the method of ascertaining the angle of flexion recommended by H. O. Thomas. To ascertain the limitation of abduction or adduction, a tape may be passed across the pelvis from one anterior spine to the other, and another tape may be held at right angles to this to indicate the normal position of the limb when straight; the limb may then be gently moved from side to side, and the degree of mobility noted. In estimating the possible amount of rotation, the hip and knee must be flexed, and the condyles of the femur grasped and rotated with one hand, while the pelvis is steadied with the other. It may be taken as a safe rule, that if flexion, rotation outwards, and abduction, can be carried to such a degree as to place the limb in the attitude assumed by a tailor when sitting cross-legged, there is no disease of the hip-joint. This position puts the round ligament firmly on the stretch, and if the head of the femur is diseased, would cause considerable pain.

4. **Suppuration** is not a necessary consequence of tuberculous disease of the hip-joint. In some cases, as we have already seen, considerable destruction may result from a process of dry caries without pus formation. But apart from this there is a considerable proportion of cases in which as the result of expectant treatment a cure is brought about in spite of the presence of considerable swelling in the neighbourhood of the joint, and possibly even a sense of deep fluctuation. In such cases it is probable that chronic suppuration has in reality occurred, the inflammatory products undergoing absorption as the result of treatment.

Frequently, however, a definite abscess forms, and gradually advances to the surface. The pus usually escapes from the capsule by perforating the posterior part which is thinnest. It then in most cases comes gradually forwards beneath the gluteus minimus and medius. Having reached the anterior border of the glutei, it passes beneath the tensor vaginæ femoris, and the upper part of the sartorius, forming a swelling in the upper part of the thigh below the anterior superior iliac spine. From this point it often burrows downwards, and opens behind the thick band of fascia into which the tensor vaginæ femoris is inserted, in the lower part of the upper third of the thigh. Occasionally the abscess escapes from the joint in its anterior part, more often towards the outer aspect. It is also a fact of practical importance that when a tuberculous focus exists in the neck of the femur it is possible for an abscess of considerable size to form in the anterior region of the hip without the joint itself being actually involved.

When the acetabulum is perforated, the abscess forms between the obturator internus and the bone, the muscle being at last extensively destroyed. The pus is confined beneath the obturator fascia, which becomes greatly thickened, and shuts off the abscess from the general cavity of the pelvis. As the pus increases in quantity, it burrows upwards, and perforates the attachment of the obturator fascia at the brim of the pelvis, coming to the surface above or below Poupart's ligament. It very rarely if ever escapes by the small sciatic notch along the course of the tendon of the obturator internus, and it never reaches the great sciatic notch, being shut off by the thickened obturator fascia. When there is extensive necrosis of the pelvic bones, the abscess may find its way into the true pelvis, and point beside the rectum or open into the bowel; but this is rare in hip disease. Still more rarely the pus may escape from the front of the joint and get into the psoas muscle, forming a psoas abscess. When this occurs, it is probably due to the existence of a communication between the synovial membrane of the joint and the bursa beneath the psoas in front of the articulation.

5. When the abscesses have burst or been opened, **Sinuses** are left, an attentive examination of the position and direction of which is of importance in forming an opinion as to the seat of the osseous disease. There are three situations in which sinuses are met with, which vary according to their point of origin from the abscess, and the position of the diseased bone:—

1. When the abscess has originated in primary synovial tuberculosis, or when the disease has commenced in the head of the femur and subsequently implicated the joint, the pus usually takes the course above described and reaches the surface below and a little in front of the great trochanter, about the insertion of the tensor vaginæ femoris into the fascia of the limb. A sinus in this situation indicates therefore almost invariably disease chiefly implicating the soft structures of the joint or the head of the femur. A similar sinus may, however, result from disease of the trochanter not extending to the joint. 2. When the sinus is in the gluteal region it may have originated in an abscess escaping from the back of the joint as above described but not extending so far downwards; not unfrequently, however, a similar sinus leads down to disease of the pelvic bones, a portion of the dorsum ilii being commonly the part involved. 3. The sinus may open in the pubic region either above or below Poupart's ligament; in this situation it is almost certainly diagnostic of disease of the pelvic bones. When it appears *above* the ligament it almost invariably leads into an intrapelvic abscess due to perforation of the floor of the acetabulum; when it opens *below* the ligament it very frequently is connected with disease of the ramus of the pubes or ischium.

It is only by attention to these circumstances that the Surgeon is enabled in many cases to form an approximate opinion as to the seat and extent of the osseous disease; for the diseased bone is often so covered in by healthy osseous structure, as when the inner aspect of the great trochanter is affected, or by inflamed and indurated tissues, that the probe cannot touch it; or the sinus may be so tortuous that a straight probe cannot follow its windings.

6. **Dislocation.**—True dislocation of the head of the femur is a rare occurrence in cases of tuberculous disease of the hip. It does, however, sometimes happen that as the result of some slight injury to the joint, actual dislo-

cation may take place, even before any extensive destruction of the articular surfaces has occurred. Such an accident is favoured by softening and ulceration of the capsular ligament, destruction of the ligamentum teres, and possibly by over-distension of the capsule with pus or inflammatory exudation. It may indeed be stated generally that in every case of dislocation of the hip occurring in a child, careful inquiry must be made as to the presence of any symptoms indicative of joint disease before the accident.

The dislocation is almost invariably of the dorsal variety, the head of the bone escaping above the tendon of the obturator internus. The limb assumes the ordinary attitude of that displacement, being shortened, flexed, adducted, and rotated inwards. In rare cases, however, when the limb has been kept perfectly extended on a splint, the head of the bone may be displaced so as to lie on the anterior part of the dorsum ilii immediately behind and below the anterior inferior iliac spine, the trochanter being directed backwards and the limb everted and extended. This position is probably always the result of treatment in which the limb has been kept perfectly extended but without sufficient care being taken to prevent eversion.

It occasionally happens when the disease commences in the femur that the whole epiphysis of the head becomes separated from the shaft and remains in the acetabulum while the trochanter is drawn upwards and rests on the dorsum ilii. In those cases the head commonly necroses and remains as a foreign body in the acetabulum, indefinitely prolonging the disease unless removed by operation.

Should true dislocation occur without the supervention of suppuration a false joint may be formed upon the dorsum ilii where the bone lodges. If suppuration is present the head of the bone will be found in a carious state, and no attempt, or at the most an imperfect one, is made at the construction of an articulation around it.

Although true dislocation is rare, a gradual displacement of the upper end of the femur in a direction backwards and upwards is very common. This is produced by the action of the muscles passing to the upper end of the thigh bone, and is a necessary result of the erosion of the head and the wearing away of the brim of the acetabulum. The result of this displacement is an increasing shortening of the limb, the summit of the great trochanter being raised a considerable distance above Nélaton's line; adduction and rotation of the limb inwards are also usually present.

In macerated specimens of this kind the upper part of the acetabulum, against which the diseased head of the femur has been lying, shows the porous spongy appearance indicative of rarefying osteitis, while the lower part, which has been relieved by displacement of the femur upwards, shows evident signs of repair, new bone having been formed which closes up the cancellous spaces, and often renders the structure more dense than natural. These appearances show that the acetabulum when affected secondarily, will readily repair if relieved from the irritation of the friction of the diseased head of the femur against it. In very rare instances of extensive destruction of the acetabulum the head of the femur has been known to slip into the pelvis.

7. **Ankylosis** may occur either with or without previous suppuration. If the joint has suppurated and the head of the bone be displaced on to the dorsum ilii, a false joint may eventually form, or osseous ankylosis in a more or less faulty position may take place. If the head of the bone continue in the

acetabulum without suppuration, osseous ankylosis may ensue with but little shortening of the limb.

Having now considered separately the principal phenomena of chronic hip-joint disease, it remains to give a brief sketch of the course of a typical case, and the methods of examination.

The first symptom that usually attracts attention is, that the child limps and walks in a peculiar shuffling, hopping manner; he does not stand firmly upon both feet, but rests on the toes of the affected limb, the knee of which is bent. This may be the only symptom when the child comes under observation, but in many cases pain of the character already described is also present (p. 415). At this stage of the disease, for the reasons already given, the patient will often refer to the knee rather than the hip as the seat of pain, and a careless Surgeon might be misled and treat the wrong joint; the more so, as there is not unfrequently a good deal of cutaneous sensibility about the inner side of the knee-joint. In examining the case the Surgeon should have the child stripped, and then note the exact position of the limb. At this early stage a varying degree of flexion at the hip is always present, and is associated with a corresponding lordosis of the lumbar spine (p. 417); at the same time there is usually abduction of the limb with slight external rotation. Viewed from behind it will be noticed that the gluteal fold on the affected side is less obvious than natural; this is the result of the flexion of the hip, and occurs independently of muscular wasting, which however develops early, and chiefly affects the gluteal region, causing flattening of the buttock. If the patient be a female the labium on the affected side will be seen to be at a lower level than on the sound one. Having observed these different points the child should be placed on its back on a flat couch, and the amount of the deformity estimated. The flexion is at once obvious if the sound thigh is bent up so as to reduce the tilting forwards of the pelvis by straightening the lumbar spine; the affected limb will then be raised from the couch to an extent corresponding to the amount of flexion which is present (p. 417). The degree of abduction is estimated by passing a tape across the front of the pelvis from one anterior superior spine to the other, and noting the angle which the affected limb forms with it. Measurement will show that no alteration in length exists, the apparent lengthening being due to tilting of the pelvis (p. 418). By gently manipulating the limb it will be found that there is marked limitation of movement in the hip, the pelvis and femur moving together. Pressure on the front of the joint and over the trochanter is painful, but it is rarely necessary to demonstrate the fact that pain is caused by forcible extension and by striking the heel or knee. In the early stages swelling may be completely absent; if present it usually occupies the upper part of Scarpa's triangle or obliterates the hollow behind the great trochanter.

As the disease advances starting pains occur at night, the muscular wasting of the limb becomes more marked, whilst steadily increasing fulness in the region of the joint indicates that an abscess is forming. This may first be detected behind the trochanter, but more often deep fluctuation is felt below the anterior superior iliac spine. Sometimes the abscess forms more internally under the pectineus muscle, and may give rise to severe pain down the inner side of the thigh by its pressure upon the obturator nerve. An intrapelvic abscess from acetabular disease usually makes its way upwards and

points at Poupart's ligament; it may sometimes be recognized by the thickening felt on rectal examination. Enlarged glands are often felt in Scarpa's triangle, or on deep pressure above Poupart's ligament.

It is about this period that the change from the abducted to the adducted position usually (p. 417) takes place, followed by true shortening of the limb. The shortening of the limb arises in chronic cases partly from want of growth consequent upon disuse, but it is chiefly due in most cases to destruction of the brim of the acetabulum and slow displacement upwards of the femur on to the dorsum ilii.

Finally, the abscesses point and burst through the skin, leaving sinuses which may continue to discharge for indefinite periods (Fig. 567). The constitutional disturbance which accompanies the progress of the disease varies much in different cases. In the early stages the health often suffers very little except from want of exercise, and possibly from the interference with

Fig. 567.—Tuberculous Disease of Hip-joint. Sinuses on outer side of Thigh.

sleep caused by starting pains. A slight but constant nocturnal elevation of temperature will often be noted.

An increase in the fever often, but not invariably, occurs when suppuration takes place. If the abscesses be allowed to open spontaneously, and decomposition to occur in the discharges, the patient will steadily waste, and eventually die from hectic and albumenoid disease. Occasionally the fatal result is preceded by tuberculous meningitis or general tuberculosis.

It must be clearly understood, however, that the course of the disease as above briefly sketched is subject to many variations. Spontaneous cure may occur at any stage—in some cases with a more or less ankylosed hip, but with little other alteration of the limb; in more advanced cases, with ankylosis, wasting and deformity. Moreover, if the disease assume the form of dry caries, considerable destruction may slowly occur with such a remarkable freedom from pain and other symptoms, that the serious nature of the case may easily escape detection.

**Diagnosis.**—In making the diagnosis of tuberculous disease of the hip, care must be taken not to confound it in its early stages with an attack of *rheumatism*, a not unfrequent mistake. The alteration in the shape and position of the limb, the obliteration of the fold of the nates, and the limitation of the pain to one joint, will usually prevent the Surgeon from falling into this error. With *disease of the knee*, care must be taken not to confound hip disease, in consequence of the pain in the early stages being commonly referred to the former joint; here the absence of any positive sign of disease about the knee, and the existence of all the signs of disease in the hip that have already been noticed, will enable the Surgeon to recognize the true seat of the affection. *Lateral curvature of the spine*, accompanied by neuralgic tenderness in the hip, occasionally gives rise to apparent shortening of the limb with pain and rigidity; but in these cases the existence of the spinal affection, the superficial nature of the pain, and the absence of increase of suffering when the joint is firmly compressed, or of painful startings at night, will indicate the true nature of the affection. *Abscess* may occasionally, though rarely, form in the vicinity of the hip without the joint being diseased. Should this take place towards the anterior aspect of the articulation under the pectineus muscle, it may, by its pressure upon the obturator nerve, occasion pain in the thigh and knee, as in those cases in which the articulation is affected; here, however, the sound state of the joint at its posterior and outer part, the absence of all obliquity of the pelvis, and of the other signs of the true hip disease, will enable the diagnosis to be made. The diagnosis from *sacro-iliac disease* has been described at p. 407. In infants *inflammation of the glands in the groin* may simulate hip disease, as the child flexes and adducts the limb, and screams when any forcible attempt at extension is made. It can be distinguished from hip disease by feeling the glands if the child be not too fat, and by observing that the thigh can be completely flexed and freely rotated without causing signs of pain. In the early stages of its formation a *psaos abscess* may be evidenced only by flexion of the hip, due to the contraction of the *psaos* muscle, whilst all the ordinary signs of caries of the spine to which the abscess is due may be absent. In such cases it will be noted that there is no limitation of the other movements of the flexed hip, and it will often be possible to detect the *psaos* abscess by abdominal palpation. Disease of the hip and disease of the spine sometimes occur together, and the difficulty of diagnosis may be great if in such a case a *psaos* abscess has extended on to the thigh, causing swelling in the anterior region of the hip.

Acute hip disease may be mistaken for *perityphlitis*. The child lies with the thigh flexed on the abdomen, and complains acutely when the right groin is pressed. The diagnosis is easily made by anæsthetizing the patient, when manipulations of the parts will reveal the precise seat of the inflammation.

It may be taken as a general rule that if the thigh can be flexed to a right angle without any movement of the pelvis, perceptible to the hand placed on the anterior superior spine and the neighbouring part of the crest, and if while in that position with the knee flexed, the femur can be abducted and rotated outwards till the heel is over the sound thigh, there is no disease of the hip. This movement is so readily made in young children that it is an easy mode of excluding hip disease, though of course if it is impossible, it does

not prove its presence, as limitation of mobility may be due to causes outside the joint.

The **Prognosis** in cases of tuberculous disease of the hip must be regarded from two points of view—1, as concerns the Life of the Patient; and 2, as concerns the Utility of the Limb.

1. **Life.**—Disease of the hip-joint, and of the contiguous osseous structures, is dangerous to life in proportion to the abundance and the long continuance of the suppuration; and this is dependent partly on the patient's constitution, but chiefly on the extent of the osseous disease. In the *synovial* form, suppuration is often prevented by rest and appropriate treatment; and when this is the case, the patient will usually recover. If suppuration take place in cases of this kind, recovery need not be despaired of; but convalescence will be greatly protracted. In such cases much will depend on the patient's constitution. If that be highly scrofulous or if there be tuberculous disease elsewhere, the prognosis becomes correspondingly bad.

When the bones that enter into the composition of the hip are the primary seat of disease, the case assumes a much graver aspect, but even then under proper treatment, there is a good prospect of cure.

In those cases in which the disease is primarily *femoral*, and dependent upon tubercle in the head of the thigh-bone, the prognosis is not so favourable, but in a considerable proportion spontaneous cure may take place under proper treatment even without operative interference.

The condition of the *pelvic bones* is one that more materially than any one other circumstance influences the prognosis in cases of hip disease. When the acetabulum is perforated intrapelvic abscess will probably form, and unless the diseased osseous structures be excised, a fatal result may be anticipated. If the acetabulum be merely superficially carious, the condition need not seriously affect the prognosis. In these cases the displacement of the head of the bone is the first step towards the cure of the disease in the acetabulum. The surface of the cavity, which is roughened, and deprived of its cartilage, speedily becomes covered by granulations, which become developed into fibrous tissue, and in a short time the whole cavity becomes filled with dense fibroid growth.

When the disease extends to the osseous structures around the acetabulum, such as the rami of the ischium and pubes, the tuberosity of the ischium and the upper lip of the acetabulum, and even the dorsum of the ilium, it usually partakes more of the nature of necrosis than of caries. In extensive pelvic disease such as this, natural means are quite unable to effect a cure, and the patient must die of hectic or intercurrent disease, unless recourse be had to excision of the head of the thigh-bone and the whole of the necrosed and carious osseous structures.

The report of the "Committee of the Clinical Society appointed to inquire into the value of excision as a means of treating disease of the hip-joint in childhood," contains the most accurate information we possess concerning the death-rate of hip disease, in the statistics furnished by Howard Marsh of the cases treated by him in the Alexandra Hospital for Hip Disease in Childhood, between 1867 and 1879. The total number of cases amounted to 401. These may be divided first into 277, or 69 per cent., in which suppuration took place, and 124, or 31 per cent., in which no abscess formed. The following table shows the results. Those classed as "verified cures" were examined by the

Committee. The value of the statistics is enhanced by the fact that the patients at the Hip Hospital are kept under treatment or watched as out-patients as far as possible until the final result is known. Patients requiring operation are sent elsewhere, and consequently are placed in a separate class.

	WITH SUPPURATION.	WITHOUT SUPPURATION.
A. Verified cures . . . . .	52	31
B. Reported cures . . . . .	33	24
C. In process of cure and still under observation . . . . .	7	5
D. Untraced :—		
a. Apparently cured on discharge . . . . .	9	15
b. Apparently convalescent . . . . .	9	11
c. In progress on discharge . . . . .	41	9
E. Indefinite cases . . . . .	5	7
F. Cases still under treatment . . . . .	14	9
G. Under treatment, apparently incurable . . . . .	3	0
H. Deaths . . . . .	87	13
I. Operations . . . . .	17	0
	277	124

These figures yield a percentage of 42·3 of cures or convalescents, 24·2 of incomplete cases, and 33·5 of deaths. Of the 87 cases in which death took place after suppuration, 16 died of meningitis, 20 died of albuminuria and dropsy, 3 of albuminuria and phthisis, 5 of phthisis, 9 of exhaustion, 2 of erysipelas, 1 of pyæmia, and 24 from unknown causes, 19 of which had been discharged as incurable. In the 13 non-suppurating cases which terminated fatally, death took place from the following causes : 7 from meningitis, 1 from phthisis, 1 from tuberculous pneumonia, 1 from croup, 1 from intercurrent disease (nature unknown), and 2 from unknown causes.

In the cases with suppuration ending in cure the average duration of treatment was about 4 years, in the non-suppurating cases it was about 3. In the fatal suppurating cases the average duration of life was 3½ years.

Of 614 cases treated at the Hip Hospital in the years 1880 to 1889, Howard Marsh was able to obtain information of only 35 deaths, which gives a mortality as low as 6 per cent. The treatment of the suppurating cases consisted in antiseptic drainage of the abscesses.

General tuberculosis is an occasional, but very rare, cause of death in cases of hip disease. Thus, of 130 cases treated consecutively in University College Hospital, death from this cause only occurred in 5 instances, whilst Howard Marsh finds that of all the suppurating cases treated at the Alexandra Hospital since 1879, only 5 per cent. have died from this cause.

**2. Utility of the Limb.**—In the most favourable cases of recovery from hip-joint disease a varying amount of lameness almost always remains. This may not be more than a scarcely perceptible limp, due to slight impairment of the mobility of the joint. In the majority of cases, however, the lameness is much more evident, and is dependent upon a greater or lesser degree of ankylosis of the hip-joint and shortening of the limb, often with faulty position. In these cases it is interesting to observe how Nature compensates for the loss of all abduction and rotatory power in the hip by giving an extremely increased degree of mobility to the lumbar vertebræ : so that the patient, in walking,

swings the pelvis from these, and thus in a great degree makes up for the loss of the natural movements in the ilio-femoral articulation. In the most extreme cases the shortened, wasted and deformed limb hangs powerless from the pelvis, suspended as it were by the ilio-femoral ligament, and slightly flexed and adducted.

Of the 83 cases of cure from the Hip Hospital verified by the Committee, 69 are described as "good cures," 11 as "moderately good," and 3 as "cures with considerable lameness."

In his Hunterian Lectures in 1889, Howard Marsh gave a full account of the condition of the limb in 76 cases which had been discharged from the Hospital, after varying periods of more than a year. Of 37 cases which had suppurated, a single sinus was present in 4; 2 walked perfectly, 22 well, 13 indifferently; mobility was perfect in 1, free in 10, slight in 7, and absent in 18; in 3 cases there was no shortening, in 17 one inch, in 12 between one and two inches, and in 3 more than two inches, the average being one inch.

Of 39 cases which had not suppurated, 12 walked perfectly, 20 well, and 6 indifferently; mobility was perfect in 9, free in 10, slight in 10, and absent in 10; in 8 cases there was no shortening, in 19 less than one inch, in 11 more than one inch, the average being two-thirds of an inch.

**Treatment.**—Nothing need be said here concerning the constitutional treatment of chronic hip disease, which must be carried out on the same principles which have already been considered in connexion with tuberculous diseases in general. No better proof can be given of the primary importance of favourable surroundings, good food and attention to the general health, than the much more satisfactory course which the disease usually runs in children of the well-to-do classes than among the poor, from whom the majority of Hospital cases are derived.

In the local treatment it is of especial importance to adopt early measures, for upon this largely depends the hope of cure with the least possible interference with the utility of the limb. As in the case of other joints, *perfect rest* and *extension* are the most essential elements in the early treatment. As a general rule it may be stated that the first step taken in the treatment should be to apply a weight extension without delay. This often at once relieves the pain and startings, and is by far the most efficient means of overcoming the flexion and lateral displacement which are almost invariably present.

In applying extension by means of a weight, the following plan should be adopted. The patient is placed upon a hard mattress. The angle of flexion and the degree of abduction or adduction are then ascertained by the methods already described (p. 417), as the extension must at first be made as accurately as possible in the line of the abnormal position the limb has assumed. A long broad strip of adhesive plaster is then applied of sufficient length to reach from a few inches *above* the knee on each side of the limb, and to leave a loop projecting beyond the sole of the foot for about one foot. In the loop is placed a piece of wood three inches in length to form a "spreader," and thus to prevent injurious pressure on the malleoli. A hole may be drilled through the spreader and the plaster covering it, and through this the cord bearing the weight is passed and secured by a knot. Narrower strips of plaster are then applied diagonally round the limb to fix the first piece more securely; great care being taken that no strip pass circularly round the limb in such a way as to constrict it. A flannel bandage is next applied from the malleoli to the

middle of the thigh, to ensure the adhesion of the plaster. A long splint is next applied to the *sound* limb; without this, although by extension the pain may be removed, adduction or abduction and some degree of flexion cannot be prevented, as the patient will turn on one side and avoid the direct pull of the weight. The long splint being fixed, the weight is applied to the rope attached to the spreader and passing over a pulley. The pulley should be fixed to some apparatus allowing of its being raised or lowered as circumstances may require. If the proper apparatus, such as is used in hospitals, be not at hand, a pulley may be readily made from a cotton-reel with a piece of wire passed through it, by which it can be slung to the back of a chair or a clothes-horse. The weight of the body serves as the counter-extension, and if necessary the foot of the bed may be raised on blocks to prevent the patient slipping down. The most convenient form of weight is a tin can filled with shot or water, till the degree of extension obtained is comfortable to the patient. The pulley and weight are to be adjusted in such a way that the extension shall act on the limb directly in the line of its abnormal position.

Fig. 568.—Apparatus for Extension by Weights in Hip-joint Disease.

To do this the diseased limb must be raised till the lumbar spine is in contact with the bed, and the degree of abduction or adduction must correspond to that noted before the apparatus was applied. During the acute stage any forced attempt to drag the limb immediately into its normal position would only aggravate the pain, but by making the extension as above described, it will be found that the limb speedily falls into the proper position. At the end of each day the pulley must be readjusted so as gradually to bring the limb parallel to its fellow. In recent cases a few days will often suffice to bring the limb into its normal position; in more advanced cases some weeks may be required. If the treatment has to be continued for any length of time, the apparatus represented in Fig. 568 may be employed. In it the pelvis and body are fixed to the bed by means of broad felt straps and buckles. A leather ankle-strap is then placed round the foot and lower part of the leg, and a padded belt above the knee. From the sides of each of these, straps are carried to a point six or eight inches beyond the foot, where they are attached to a transverse iron rod, four inches long. From this the cord suspending the weight passes over a pulley-frame fixed to the end of the bed. The weight applied should be from two to three pounds in children up to six years

of age ; four pounds between the ages of six and ten ; five or six pounds from ten to thirty.

The period during which the weight extension should be applied has already been considered at p. 426. At the end of the time the Surgeon must decide what are the means best adapted for the maintenance of perfect rest in the joint, which will be required for at least a year. If the patient's surroundings are such that he will not be deprived of fresh air by being kept in the recumbent position for some weeks at least, this is certainly the most efficient treatment. In adults a long splint may be applied as for fractured thigh.

Fig. 569.—Thomas's Splint applied.

Fig. 570.—Thomas's Splint.

This is, however, of little use in children, as they always manage by twisting the body to maintain a considerable degree of flexion with adduction or abduction. Hamilton's double long splint (Fig. 218, Vol. I., p. 622) should therefore be used, by which a much better position is obtained. Weight extension can be applied with this if required.

Thomas's splint (Figs. 569, 570) is by far the best apparatus yet invented for the treatment of all forms of hip disease. It may be applied at any stage, and should be worn till the cure is complete. It will, however, generally be found most convenient, when there is considerable abduction or adduction with *acute pain* in the early stages of the disease, to correct this by means of the

weight extension used as above described before applying the Thomas's splint. Thomas's splint is the only apparatus that maintains absolute rest of the joint, while at the same time the patient is able to move about during the whole or the greater part of the treatment. The splint consists of a flat bar of soft iron, varying from three quarters of an inch to an inch and a half in width, and from three-sixteenths to three-eighths of an inch in thickness, according to the age, size, and weight of the patient. This bar must be long enough to reach from the lower angle of the scapula to the middle of the leg immediately below the prominence of the calf. The upper and lower parts must be straight to fit the back and the leg, and between these it must be bent into a curve accurately fitted to the buttock of the patient. To this vertical bar, three curved transverse bars of soft iron about  $\frac{1}{2}$  inch thick, by 1 to  $\frac{3}{4}$  inch, are fixed as in Fig. 570. The upper of these should be of sufficient length to embrace the chest about as far as the nipple on each side. The middle bar should be immediately below the curve for the buttock in the vertical bar. If it be placed too low, the splint is more apt to twist round and allow flexion. The whole apparatus is padded with a thin layer of felt, or flannel, covered with leather. The splint is applied in such a way that the curved part of the vertical bar lies midway between the tuberosity of the ischium and the great trochanter. The curved parts are then bent so as to fit the chest, thigh, and leg comfortably. A strong piece of bandage is passed through the rings in the ends of the chest-piece, and tied firmly. A broad body-bandage of swan's down calico, or flannel, is then wound round the vertical bar, so as to get a good hold of it, and carried two or three times round the body. A narrower bandage is next applied to the thigh and leg. If the patient is to walk about, braces of strong calico must be fixed to the chest-piece, and carried over the shoulders, otherwise the splint will slip down. If there is much flexion, the splint may be bent forwards immediately below the buttock curve to a degree a little less than that of the limb, which may be allowed to lie upon it with the knee slightly bent. In this position it is secured by a few turns of bandage round the thigh and leg. In a few days, if the patient be kept on his back, the weight of the limb will have extended the hip, so that the whole leg is uniformly in contact with the splint, which may then be straightened a little; this is repeated until the flexion is corrected. The vertical bar must never be bent opposite the knee. If there is much adduction, it is often convenient to twist the vertical bar, so that its anterior aspect looks very slightly outwards from below the buttock. These alterations in the shape of the splint must be carried out by the Surgeon himself with strong iron wrenches made for the purpose. A little experience is required in the manipulation of these splints, but the necessary skill is easily acquired, and will well repay the Surgeon for the trouble involved in so doing. The splint must be worn continuously day and night till all symptoms have subsided, often for two or three years. In walking with crutches, the patient is raised by a patten on the foot of the sound limb, so that the opposite foot does not touch the ground (Fig. 569). Should suppuration take place, Thomas's splint is still the most convenient apparatus, as it leaves the parts uncovered in which the abscesses point. One great advantage in the splint, is that under the superintendence of the Surgeon, any blacksmith can do the iron-work, and any saddler the padding, and it is thus equally available for country or city practice.

After all acute symptoms have disappeared, Thomas's splint is still the best

apparatus, but sometimes the joint may be conveniently fixed by means of a leather splint, the starched bandage, or the plaster of Paris bandage. Of these I prefer the starched bandage as being most easily applied. The hip part must be strengthened with a piece of pasteboard lined with calico, sufficiently long to extend down the whole of the back of the thigh to below the knee, so as to support that joint also, and the spica bandage must be applied in repeated turns, otherwise the apparatus will not fix the joint. In applying this or any other apparatus, it is often necessary, especially in children, to administer chloroform, as the pain occasioned by the necessary movements may be too severe to be borne without it.

In young children a single Thomas's splint is not an efficient appliance, and it is very essential that the lower limbs be fixed so that tilting of the pelvis may be prevented, and in order that the child may be easily carried about without fear of moving the inflamed joint. For this purpose a double Thomas's splint should be employed. This consists of a vertical bar for each lower limb which is attached above to the circular band; the leg pieces should be fixed in such a position that the limbs are slightly abducted.

The above description includes the general plan of treatment required in the early stages of tuberculous disease of the hip, and, although different Surgeons may employ various methods for carrying out the treatment, their object is the same, viz., to bring about arrest of the disease by putting the joint at perfect rest, relieving muscular spasm by extension, and improving the condition of the general health.

In spite of every precaution, however, suppuration occurs in a considerable proportion of cases, and unfortunately has often already taken place when the case is first brought for treatment. Under these circumstances a wide difference of opinion exists amongst Surgeons at the present day as to the line of treatment which should be adopted. It is at once obvious that the success of the method adopted must be judged chiefly by the amount of danger which it involves to the life of the patient, and by the ultimate utility of the limb. Preference must also be given to that method which, without sacrificing any of the advantages to be obtained in other ways, brings about the most speedy cure. The treatment must as far as possible be based upon general pathological principles, but theoretical considerations must not be allowed to outweigh practical experience; the perfection of the treatment must be judged by the perfection of the result.

Thus far all Surgeons will agree that when once suppuration has occurred in a case of tuberculous hip disease the sooner the abscess is opened with antiseptic precautions the better. But whilst some Surgeons consider this sufficient, and maintain that the best ultimate result is obtained by opening fresh abscesses as they form, and keeping the joint at perfect rest, others believe that an attempt should be made to remove the diseased tissues as freely as possible, and for this purpose practise excision of the head of the femur at a comparatively early stage of the disease. Attempts have been made by Schede and others to extend the operation of **arthrectomy** to the hip-joint, and in cases of synovial disease to remove the tuberculous tissues as completely as possible without sacrificing the head of the bone. Such an operation must necessarily be extensive, and probably imperfect, and although in rare instances an extensive abscess in connexion with disease of the upper end of the femur or of the pelvic bones in the neighbourhood of the acetabulum may

be thoroughly treated without interfering with the joint itself, yet in the large majority of suppurating cases the choice must lie between merely opening the abscess and proceeding at once to excise the head of the femur.

**Indications for Excision.**—In endeavouring to arrive at a conclusion as to the practical indications for the operation of excision in tuberculous hip disease, it will be gathered from what has been said above that we have to consider the relative merits of two very different lines of practice, and to answer if possible the question “Is excision to be regarded as the treatment to be more or less generally adopted in suppurating cases, or is it to be reserved for exceptional cases which have resisted all other methods?”

Those Surgeons who regard excision as a practice to be avoided if possible, base their opinion chiefly upon the utility of the limb which is obtained. Thus, Howard Marsh, who has most ably supported the expectant treatment, is strongly of opinion that the final result thus secured is better than in cases treated by excision in the earlier stages of suppuration. Marsh recommends that the abscess should be freely opened and a drainage tube inserted for two or three days, antiseptic precautions being of course rigidly observed. Absolute fixation of the joint is maintained throughout the treatment, and any fresh abscesses which may subsequently form are similarly opened. The results obtained by this method of treatment have already been given both as regards the mortality and the subsequent condition of the limb in the cases which recover (p. 425).

Among the most ardent advocates of early excision—that is, excision practised as an operation of choice in suppurating cases, as opposed to excision reserved for exceptionally severe and unfavourable cases—may be mentioned Annandale, Croft, Barker, and Wright. In this mode of treatment the abscess is, in the first place, freely opened, and the track by which the abscess has escaped from the joint is sufficiently enlarged to allow examination of the head of the bone. If, as is almost invariably the case, this is found diseased, with separation of the cartilage and caries of the surface, it is removed by sawing the bone through the neck. In this way not only is the diseased head itself removed, but free access is obtained to the joint, so that an endeavour may be made thoroughly to remove tuberculous synovial membrane, to treat any acetabular disease which may exist, and in some instances to afford free drainage to an intrapelvic abscess. The methods of treating the wound and obtaining primary union will be subsequently considered, but it may here be stated that after the adoption of this line of treatment a Thomas's splint should be worn for at least a year.

In comparing these two methods it certainly appears that on theoretical grounds excision may be supported as being the only practical means of removing the diseased tissues. As regards the mortality attending the two methods, it is probable that the difference is inconsiderable, for the immediate fatality of excision in the early stages of suppuration is small, and the subsequent mortality is probably little affected, although the patient escapes those dangers which are inseparable from the presence of discharging sinuses. Again, the duration of the treatment will not be found to be shortened by early excision to the extent that was at first anticipated. In the most favourable cases at least a year must elapse before the patient is allowed to use the limb, and in the majority of instances one or more secondary operations for sinuses will be required before a cure is obtained. So far, therefore, it is

difficult to decide between the two methods : and when, lastly, we compare the utility of the limb obtained by expectant treatment with that after excision, we still find considerable difference of opinion as to the relative merits of the two methods. As far as the ultimate shortening of the bone is concerned, it matters little whether the head is slowly removed by caries or at once by excision, and it is also certain that removal of the head often produces not more than half an inch of shortening, and probably has little effect on the subsequent growth in length of the bone. The more rapid the cure the less will be the faulty development of the limb resulting from disuse. A movable joint is more often obtained after excision than after expectant methods, but in some cases the joint is weak, and has a tendency to become flexed, so that it is doubtful whether, as far as practical utility is concerned, the more fixed joint is not eventually the more serviceable to the patient.

The evidence on the whole is, indeed, by no means convincing, and although

Fig. 571.—Perforation of Acetabulum in Tuberculous Disease of Hip.

Fig. 572.—Carious Head of Femur from the same case.

the balance may perhaps turn in favour of avoiding excision in the earlier stages of suppuration, unless there are strong indications for performing it, the operation should certainly not be regarded merely as a last resource in advanced cases. It is only by the careful observation of series of consecutive cases that a final decision upon this important question can be made. It is however, possible to indicate certain conditions in which the Surgeon should not hesitate to undertake the operation. In the first place if the head of the bone is extensively destroyed by caries, if a sequestrum is present in its surface, or if there is considerable disease outside the epiphyseal line, the joint itself being involved, excision through the neck should be performed. Secondly, in the rare instances in which the head of the femur is completely separated, and lies as a loose sequestrum in the cavity of the acetabulum, the sooner the dead bone is removed the better. This condition is not easy to recognize until the abscess is freely opened and digital examination made. Thirdly, in cases of primary acetabular disease, especially when sequestra are

present, or when perforation has occurred with the formation of an intra-pelvic abscess the condition can seldom be recovered from unless the head of the bone is removed. This is often itself extensively diseased (Fig. 571, 572), but apart from this it is only possible to treat the diseased acetabulum efficiently and drain any existing abscess by removing the head of the bone. Fourthly, in the later stages of the disease when septic sinuses are present, and the patient is suffering from hectic, excision is usually an imperative necessity. The operation is then undertaken as an alternative for amputation, which is here too formidable a proceeding to be undertaken except in the last extremity. Lastly, the operation may be required in old-standing cases when sinuses are present and the limb is in a flexed or otherwise deformed position. By the application of a weight extension the malposition may sometimes be corrected and by laying open and scraping the sinuses they may be healed. Often, however, excision is required, and serves the double purpose of curing the sinuses and bringing the limb into a satisfactory position.

The question of **Amputation** in cases of disease of the hip-joint is one that must often have presented itself to the Surgeon when he has contemplated the shortened, wasted, and deformed member that is sometimes left after the more advanced forms of the disease, and which can never be rendered useful as a basis of support to the body by any mechanical contrivance, however skilfully designed, but must always remain a useless and cumbrous appendage.

It appears to me that this operation is justifiable, and, indeed, is to be advocated in the following circumstances :

1. In cases where the disease is confined to the head of the femur, or where, if any portion of the pelvic bones be attacked, it is to so limited an extent as to be readily removable by the gouge, excision would necessarily be the usual practice. But if the patient's health be too low to bear this, or if the limb be so shortened, atrophied, and deformed by long disuse as to be incapable of furnishing proper support, then amputation at the hip-joint would, I think, be a proper procedure. I do not think that the mere destruction of the cartilaginous lining of the acetabulum should be an argument against the performance of the operation ; for we constantly see in hip-joint disease when the head of the bone has been dislocated, or after amputation at the hip-joint for accident or ordinary disease, that the acetabulum is filled up with a dense fibroid mass after the destruction or removal of its cartilage. But, if the pelvic bones be so far diseased that the necrosed or carious part does not admit of removal, then necessarily amputation would not be justifiable.

2. When the disease involves the shaft of the femur, which may be necrosed, or atrophied to such an extent as not to leave a sound limb after the removal of the upper epiphysis, amputation would be proper.

3. Amputation would be justifiable after excision has been tried and has failed in securing a useful result to the patient, the limb being left short, weak, loose, and œdematous.

4. In a few instances amputation has been successfully performed when, after excision, the discharge from the sinuses had continued and albumenoid degeneration of the viscera had set in. Cases have been recorded by Marshall and Barwell, in which, after the operation, the size of the enlarged viscera sensibly diminished, and the general health greatly improved.

5. Excision of the hip is occasionally followed by osteomyelitis of the femur,

and necrosis of the shaft. Should the patient survive till the process becomes chronic, amputation affords the only chance of life. The operation was successfully performed under these circumstances a few years ago in University College Hospital.

**EXCISION OF THE HIP-JOINT.**—White of Manchester, in 1769, was the first to propose, and Anthony White, of the Westminster Hospital, in 1821, was the first to perform, excision of the head of the femur. This he did on a boy eight years old, who had had disease of the hip-joint for three or four years, and in whom the carious head of the thigh-bone rested on the dorsum illi. White removed the head and trochanters of the bone, and the patient recovered from the operation, dying of phthisis five years afterwards. The preparation is in the Museum of the College of Surgeons. This operation was repeated by Hewson of Dublin, in 1823; it then seems to have been forgotten in Great Britain until its revival, in 1845, by Fergusson. But in the meanwhile it had not entirely escaped the attention of Continental Surgeons. Oppenheim, in 1829, and Sentin, in 1832, excised the head of the femur for gunshot injury; and, in 1842, Textor published an essay on the subject.

**Methods of Operating.**—The method employed will vary somewhat according to the stage of the disease in which the excision is undertaken, and the probable amount of bone which it is necessary to remove. In the earlier stages of suppuration the anterior incision, as recommended by R. W. Parker, is especially useful, as in this way the joint is reached by the route along which the abscess usually comes to the surface, no muscles or other important structures are divided, and through this incision the bone is easily sawn through its neck. In the later stages of the disease, especially when there is marked flexion associated with backward displacement of the upper end of the femur, the operation is most conveniently done through an external or posterior incision, which has the additional advantage that through it division of the bone below the trochanter can easily be practised. When sinuses are present the incision can often be modified so as to pass through those which appear to lead down to the joint.

**Anterior Incision.**—The incision is commenced half an inch below the anterior superior iliac spine, and is continued downwards and slightly inwards for three inches. By deepening the incision the sartorius and rectus femoris on the inner side are separated from the tensor vaginae femoris and the gluteus medius and minimus on the outer, and thus the front of the joint is reached. In the majority of cases this incision will freely open an abscess external to the joint. The details of the further steps of the operation may best be conducted on the lines laid down by A. E. Barker and Bilton Pollard. The cavity of the abscess should be thoroughly scraped and flushed by means of Barker's flushing curette (Fig. 573) with water at 105° to 110° F. which has been sterilized by boiling. The track by which the abscess has escaped from the joint is now enlarged if necessary, and the head of the bone is excised by sawing through the neck in the line of the incision with an Adams's saw (Fig. 574). The loose head is easily removed with a curved periosteal elevator, or with sequestrum forceps.

The cavity of the joint is next thoroughly scraped and flushed until the tuberculous tissue has been removed as completely as possible. Special care must be taken to remove any necrosed cartilage from the acetabulum, and

clean out any foci of disease which may be present in the bone. Pollard has found it useful finally to examine the depths of the cavity with a strong light thrown into it from a forehead mirror. All hæmorrhage must be arrested as thoroughly as possible. The whole cavity is now thoroughly treated with iodoform emulsion (Vol. I., p. 264), and plugged with one or more sponges. The sutures having been inserted, the limb is held in an abducted position, and the sponges removed; the sutures are then tied. Barker does not as a rule use a drainage tube, but the introduction of a small tube for forty-eight hours as advised by Pollard does not materially delay the healing and prevents any risk of the wound becoming distended with blood. Firm elastic pressure should be secured by a wool dressing and spica bandage. The limb should be

kept in a slightly abducted position on a double Thomas's splint. In the majority of cases primary union can be obtained under a single dressing. The objection which has been raised to the anterior operation that the drainage of the wound is imperfect is thus not a serious one.

#### External Incision.—

Langenbeck recommends excision by a straight incision over the great trochanter in the long axis of the limb; it is about four and a half inches in length, and is so placed that the summit of the trochanter is at the junction of its middle and lower thirds. The incision having been carried down to the bone the joint is opened; the muscles are detached from the great trochanter with the knife which cuts close on to the bone. Finally, the head is turned backwards out of the acetabulum, and the saw applied either through the neck of the bone or below the trochanter. In some cases this operation may be performed subperiosteally.

**Posterior Incision.**—In cases in which the situation and extent of the sinuses leave the Surgeon a free choice for the situation of his incision, the plan recommended by Sayre will be found to give excellent results. A semilunar incision is made with its concavity forwards, commencing above the great trochanter midway between it and the crest of the ilium and carried downwards behind the bone. The first incision must go directly down to the bone through the periosteum. The soft parts are then pulled forwards, and the periosteum

Fig. 573.—Barker's Flushing Curette.

Fig. 574.—Adams's Saw.

divided by means of a small but strong curved bistoury as far as possible round the bone below the trochanter, in a direction at right angles to the lower part of the first incision. The Surgeon then peels the periosteum with the muscles attached to the trochanter off the bone with a strong periosteal elevator. The joint is next thoroughly opened, and the head of the bone turned out, by which the periosteum is peeled off from the inner side; lastly, the bone is sawn through above the small trochanter. By saving the periosteum, Sayre states that he obtains more perfect repair with less shortening, and a stronger and more movable joint.

In sawing the bone in excision of the hip, the ingenious instrument

Fig. 575.—Gowan's Osteotome.

invented by Gowan of Guy's Hospital will be found very useful in some cases (Fig. 575).

Excision may also be done through a T-shaped incision over the upper end of the thigh bone, and in some advanced cases when the gluteal region is perforated with sinuses, the soft parts thinned and the head of bone displaced on to the dorsum ilii, it is sufficient to pass a director down one of the chief sinuses leading to the carious bone, and to slit this up. It is usually unnecessary to employ the bloodless method in these operations, but it has the advantage of enabling the Surgeon to ascertain accurately the condition of the trochanter and upper end of the femur. The tourniquet may be applied as represented in Fig. 10, Vol. I. When the trochanter is healthy the bone should, as a rule, be sawn through the neck; if diseased, above the small trochanter. If, however, there is irreducible flexion in old-standing cases, or if the presence of the trochanter interferes with the free drainage of an intra-pelvic abscess, the bone may in any case be sawn below it.

Where large portions of the pelvic bones require removal, external or posterior incisions should be made in the way already described; the incisions, however, being made more freely, but not carried so far forwards as to endanger the anterior crural, or so far back as to wound the sciatic nerve. After the removal of the head of the thigh-bone, all loose necrosed pieces are to be taken out, and then, by means of ordinary cutting or gonge-forceps, the acetabulum and other carious osseous structures are cut away piecemeal.

Those portions of bone which have necrosed are usually lying loose, or else may generally be readily separated by the finger, or by the handle of a scalpel, from the subjacent soft structures.

Fig. 576 represents the result obtained in a girl from whom I removed the upper end of the thigh-bone, the acetabulum, the rami of the pubes and of the ischium, a portion of the tuber ischii, and part of the dorsum ilii. This patient, when admitted into the Hospital, was in the last stage of disease, exhausted by constant discharge, and must inevitably have speedily sunk had no effort been made to remove the cause of prostration. At the operation she was so exhausted that it was necessary to leave her on the operating-table for

Fig. 576.—Result of Excision for Extensive Acetabular Disease, three years after Operation.

some hours before she was sufficiently restored to bear moving into bed. Nevertheless, by the free use of stimulants and nourishing food, she improved rapidly; and when she recovered, the limb presented the appearance in the drawing: it was straight, shortened about two inches; good movement existed at the hip; and she could walk with much ease. Constitutionally, she was in perfect health, and continued so up to the time when she was last seen, about fourteen years after the operation. In three other cases I have successfully removed large portions of the acetabulum and of the contiguous portions of the ilium and ischium. In cases such as these, if they are left to themselves, the result must inevitably be fatal. There is no danger of laying open the pelvic cavity during the removal of these masses of pelvic bone; for, during the progress of the disease the fasciæ and muscles lining the pelvis become so thickened that they form a barrier which effectually protects the pelvic cavity.

In children a double Thomas's splint is the most convenient apparatus for

use after excision of the hip ; if this has been done by a posterior incision the piece of the splint opposite the wound must be cut out. In adults a Thomas's splint, or during the early stages a bracketed long splint, may be used. Often, however, it is convenient to dispense with the use of a splint altogether, applying a weight extension and preventing rotation by two soft iron cross-bars fixed to the leg with a plaster of Paris bandage.

The **Results** of excision of the hip have already been partly discussed (see p. 424, *et seq.*).

1. The *Mortality* due to the operation necessarily varies according as it is undertaken as an operation of choice in the earlier stages or as a last resource in advanced cases. Leisrink of Hamburg published in the *Archiv für klinische Chirurgie* (1870) the statistics of 176 cases. In 24 of these, or 13·6 per cent., death occurred from intercurrent diseases—mostly pyæmia (11) and septicæmia (2). Fourteen patients, or 8 per cent., died within a fortnight from exhaustion ; 14 others died between this time and the end of the first month—most from exhaustion, one from amyloid disease, and two from phthisis. From the beginning of the second month to the end of the year after the operation there were 27 deaths, or 15·3 per cent. ; while nine died in the course of two or more years, of phthisis and other diseases. Leisrink states that in the 176 cases there were altogether 98 deaths. Of this apparently high mortality, however, only about one half, or 26 per cent. of the whole cases, could be ascribed to the operation itself. The other half of the deaths were produced by extension of the disease, by diarrhœa, or by phthisis or other disease of internal organs—probably in many instances existing at the time when the operation was performed.

The mortality following the operation appears to have been much lower in England and America than in France and Germany. In 1881 Croft published the statistics of 45 cases operated on by himself ; of these 19 recovered, 18 died, and 8 were still under treatment at the time of the report. Of the 40 per cent. of deaths, 15·6 died directly from the operation, 13·4 from some form of tuberculous disease, 6·6 from albumenoid disease, and 4·4 from causes unconnected with the joint affection. Of 203 cases of excision collected by the Committee of the Clinical Society, 29, or 13·7 per cent. died directly from the operation.

Wright of Manchester, has recorded 100 cases performed by himself up to 1887, in 30 of which the operation was done nine months or less after the onset of the disease. The total number of deaths was 13, but only three patients died of the direct results of the operation, though two others died shortly after the excision of pyæmia, resulting from previous incision of the joint.

Of 36 cases recorded by Bilton Pollard in 1892, in which the operation was performed by the method described at p. 434, eight or 21·6 per cent., were known to be dead. Four patients, or 10·8 per cent., died soon after the operation ; in one of these cases the operation was very prolonged, and in another, collapse occurred when the hot water flushing was commenced, the child dying three hours afterwards ; in another, death was entered as due to iodoform poisoning, and the fourth case died collapsed on the eighth day. Of the other four cases, two died from causes unconnected with the hip disease—one from heart disease, and one from diphtheria ; the third died of tuberculous meningitis, and in the fourth case, death, attributed to abscess of the brain, occurred three and a half years after the operation.

The result of my own experience is, that the mortality directly referable to the operation itself is but small.

2. The *Utility of the Limb* after excision has already been partly considered (see p. 425). After a successful operation performed in the late stages the shortening usually amounts to two or three inches. The limb is well-nourished, straight, firm, and allows easy and rapid progression. The ankylosis is fibrous, not osseous. The patient is thus enabled to flex the thigh on the pelvis, and to adduct it; but, just as in cases that have undergone a natural cure, the power of external rotation and of abduction is lost, the mobility of the lumbar spine compensating for the loss of these movements.

The best available evidence as to the utility of the limb after excision in the earlier stages of suppuration is afforded by a study of sixteen completed cases in Pollard's list already referred to. Of these, two may be excluded as both hips were excised, and another which was not seen later than a year after the operation. In four cases three years or more had passed before excision was performed; the real shortening varied from  $1\frac{1}{2}$  to  $3\frac{1}{2}$  inches; three walked well, and one "not well." In the remaining nine cases the average time which had elapsed between the onset of the disease and the operation was  $15\frac{1}{2}$  months; the shortening, after periods varying between twenty-two months and five years and a half after the operation was from 1 to  $2\frac{1}{4}$  inches (average  $1\frac{1}{2}$  inch); in 6 there was more or less movement, and in 3 ankylosis; and in 2 there was permanent flexion; 3 walked well on the sole, 3 walked well on the toes, 1 walked fairly well, 1 walked well with a stick, and 1 preferred to use a stick but could walk well without it.

More evidence of this kind is required before the question of the expediency of performing excision as an operation of choice in suppurating cases can be definitively decided.

#### ANKYLOSIS OF THE HIP.

**Ankylosis of the Hip-joint**, following inflammation, differs in its completeness and in the position of the limb. Thus, it may be fibrous or osseous: or the limb in either of these cases may be extended, flexed or adducted.

The most important point is the *direction of the limb*. When the joint is completely ankylosed with the limb fully extended and straight, nothing can be done to improve the patient's condition. The lumbar spine will acquire increased mobility, especially in a rotatory direction, and the patient will stand and walk with ease. The chief difficulty arising from the position of the limb will occur in going up stairs and in sitting.

If, however, the ankylosis be fibrous, even though the limb be straight, the freedom of movement may be much increased, and any faulty direction as to abduction or adduction may be in a great measure remedied, by douches, friction, pressure, or even forcible movement, and occasionally by the subcutaneous section of tense bands of fascia, or of tendinous and muscular structures about the anterior superior spine of the ilium.

If, unfortunately, the limb have become ankylosed in the flexed position, means must be adopted to straighten it; and this must be done whether the ankylosis be fibrous or osseous. For here the deformity and inutility of the limb are always considerable; and increasingly so, the more the ankylosis approaches to a right angle.

In rectangular ankylosis of the hip, the foot cannot be put to the ground so long as the spine is straight (Fig. 577). In order that the toes should touch the ground, it becomes necessary that the body be bent forward; and the lumbar spine will consequently be thrown into a very considerable arch (Fig. 578).

The extent of the angular deformity in this kind of ankylosis can always be easily measured in the following way. If the patient be laid flat upon his back, so that the lumbar spine touches the mattress on which he is lying, the knee will be raised above that of the sound limb, and the angle formed between the thigh and trunk will at once be very perceptible. But if the knee be depressed so as to be brought to the same level as that of the sound limb, then the anterior superior spine of the ilium is rotated forwards, and the lumbar spine arched forwards to an extent proportionate to the angle of deformity.

This angular ankylosis of the hip-joint requires to be corrected, and the limb to be brought into a straight position, so that, even if it be shortened, the patient may, by means of a high-heeled boot, rest it upon the ground, and use it as a means of support and of progression. This may sometimes be effected,

Fig. 577.—Ankylosis after Hip-joint Disease : Flexion of Limb on Pelvis.

Fig. 578.—Ankylosis after Hip-joint Disease : Curvature of Spine in placing Foot on Ground.

when the ankylosis is fibrous, by forcible extension under chloroform. But in other cases this cannot be done by simple extension, resistance being offered by the muscles on the anterior and upper part of the thigh. In such circumstances, those that offer most resistance must be divided subcutaneously; and these will usually be found to be the rectus, tensor vaginae femoris, pectineus, and gracilis. After the limb has, in this way, been straightened, and maintained for some time in the straight position by means of the long splint, weight apparatus or Thomas's splint, passive motion and frictions may be used to restore the mobility of the joint.

**Operation for Angular Osseous Ankylosis.**—Division of the upper end of the femur for angular ankylosis was first performed by Rhea Barton, in 1826. It was done in the case of a sailor, 21 years of age, who, in conse-

quence of an injury, had osseous ankylosis of the hip in a nearly rectangular position. Barton, according to Gröss, made a crucial incision over the great trochanter. The muscles were detached and turned aside, and the great trochanter and part of the neck of the femur were sawn transversely. Whether a simple section of the bone was made, or, in conformity with Barton's usual practice in ankylosis, a V-shaped piece of bone was removed, I know not; for on this point American authorities differ. But the limb was brought into a straight position, and put up in a fracture apparatus for twenty days. Passive motion was then commenced, and at the end of four months the patient had a movable false joint, so that he could rotate the limb, abduct it for twenty inches, and carry it backwards and forwards to a still greater extent. The case was therefore eminently successful. The operation appears, however, to have attracted but little notice, and to have been but rarely performed by others. It is true that Barton himself operated a second time; and that Rogers of New York, in 1830, did so successfully on a man 47 years old. The example of these American Surgeons was followed in Europe, by Textor in 1841, and by Maisonneuve in 1847, on a girl of 18, successfully. Ross (U.S.A.) operated

Fig. 579. — Lines of Section in Sayre's Operation for Ankylosis of Hip-joint.

Fig. 580. — Application of Saw to Neck of Thigh-bone in Adams's Operation.

in 1857 on a woman of 23. In the two latter cases no false joint was made; but the bone, after being straightened, united again by callus. In March, 1869, I performed a similar operation at University College Hospital, on a girl of 16, who had rectangular osseous ankylosis of the right hip-joint. The patient made a slow but good recovery with a straight and useful limb. There was no attempt at the formation of a false joint, but consolidation took place at the line of section.

In 1862 Sayre recommended division of the femur above the small trochanter so as to retain the attachment of the psoas and iliacus to the shaft, and he aimed at the production of a false joint by cutting out a semicircular piece of

bone with its convexity upwards, and then rounding off the upper end of the femur (Fig. 579).

As a matter of fact, however, bony union usually occurs after osteotomy, and the result is good if the femur can be brought down into a satisfactory position. The division above the small trochanter has therefore no special advantage, and choice must usually be made between division of the neck of the femur as recommended by William Adams, and division of the shaft below the small trochanter as advised by Gant. The former method is available only when ankylosis has occurred without extensive destruction of the head of the bone. It is done as follows :—

A tenotome, having been introduced a little above the top of the great trochanter, is carried straight down to the neck of the femur, dividing the muscles and opening the capsule freely. The knife being withdrawn, an Adams's saw (Fig. 574) is passed down to the bone, which is cut through from before backwards (Fig. 580). The section of the bone takes a few minutes, and is as much an act of filing as of sawing. The wound is then closed by a pad, and the limb brought straight. Before this could be done in Adams's first case, it was necessary to divide the long head of the rectus, the adductor longus, and the tensor vaginae femoris muscles. In performing this operation, as Adams justly observes, it is of great importance for the Surgeon to bear in mind the altered direction of the shaft of the femur, which is usually adducted as well as flexed forwards, so that the division of the neck may be made at right angles to the axis of the bone and not obliquely, or in a direction more or less parallel to the shaft. After the operation in Adams's first case, an endeavour was made by passive motion to get a false joint ; but this being unsuccessful, the attempt was abandoned, and the limb allowed to ankylose in the straight position. Since this case, the operation has been repeated successfully by Adams and by many other Surgeons, some of whom prefer to use an osteotome instead of a saw.

Fig. 581.—Cross-legged Deformity. Lucas's case.

In performing osteotomy of the femur below the small trochanter, a short incision is made on to the external surface of the bone which is then divided with a saw or osteotome.

**Cross- or Scissor-legged Deformity** is occasionally met with as the result of ankylosis of both hip-joints. The annexed drawing (Fig. 581), which Clement Lucas has allowed me to take from one of his cases illustrates admirably the peculiar position assumed by the lower extremities in this remarkable deformity. It will be noticed that neither limb is in the ordinary adducted position of hip disease, both being fully rotated outwards. Its mode of origin is somewhat obscure. The view to which Lucas inclines is probably the correct one, viz., that the position is assumed, probably unconsciously on the part of the patient, with the object of placing the limbs in the most favourable positions for progression. One leg is usually affected first ; after a time the other follows. Progression is from the knees, not from the hips. The two limbs usually become

equally affected; but in a case that I saw with Tyson, of Folkestone, the left was crossed over the right, the latter being nearly straight. Should it be thought desirable to attempt to correct this deformity, an anæsthetic should be given, and if the ankylosis is not perfect, the adhesions must be broken down and the limbs straightened. If the ankylosis is osseous, the neck of the femur on either side must be cut across with saw or osteotome, and the limbs brought into position.

#### DISEASES OF THE FEMUR.

In connexion with the various diseases of the femur little need be added to what has been said already in describing the affections of the bones in general. Acute necrosis of the bone is not uncommon, and shows a special predilection for its lower extremity, causing the separation of a sequestrum from the popliteal surface. Chronic osteitis and periostitis of the shaft are also not unfrequently met with. Many special points relating to sarcoma of the femur have already been considered. Tuberculous disease of the articular extremities is chiefly important in its relations to the similar affections of the hip and knee, but may occur independently of joint disease.

**Tuberculous Disease of the Great Trochanter** occasionally affects the bone primarily, or may have its starting-point in one of the overlying bursæ. The resulting abscess in the upper and outer part of the thigh may closely resemble that due to hip disease; but careful examination will usually show that the joint is unaffected, and that the disease is limited to the trochanter. It is more common in children than in adults, and results in central or superficial caries, which is often associated with necrosis. In these cases the limb should be made bloodless, and the trochanter fully exposed by a curved incision (Fig. 582). The disease must then be treated on general principles, but great care must be taken not to open the joint.

Fig. 582.—Incision exposing the Great Trochanter for the removal of diseased bone: Esmarch's bandage applied to render the operation bloodless.

**Tuberculous Disease of the Neck of the Femur** is a common antecedent of hip disease, but may sometimes give rise to an extra-articular abscess by the early treatment of which the joint may be saved. Two cases of this kind have been recorded by Charters Symonds. In both cases a large abscess was present in the upper and outer part of the thigh, from which a minute sinus led to a sequestrum in the neck of the femur. The removal of the sequestrum was followed by recovery in both instances, in one with a perfect joint.

## DISEASES OF THE KNEE-JOINT.

Nothing further need be said here concerning most of the various diseases to which the knee is liable. Acute synovitis, acute arthritis, rheumatoid arthritis, and Charcot's disease are relatively so common in the knee that our knowledge of their clinical and pathological features is largely derived from a study of them in this articulation. Certain special considerations are, however, necessary relative to tuberculous disease.

**Tuberculous Disease of the Knee-joint.**—The knee is more commonly the seat of tuberculous disease than any other joint in the body, excepting perhaps the hip. To the disease of this joint the name of "white swelling" was first applied, and in many respects it stands as the type of tuberculous joint affections in general.

In young adults the cases of primary synovial disease equal, if they do not exceed, in number those in which the joint is infected from a primary osseous deposit. The statistics of Willemer, König, and Cheyne, show, however, that as age advances the proportion alters, primary synovial disease becoming much more rare. Cheyne finds that in cases commencing as a tuberculous bone deposit, this most often occurs in the lower epiphysis of the femur, especially in the internal condyle; next in frequency in the head of the tibia, and most rarely in the patella. Kocher has described a variety of the disease which he believes commences in one of the semilunar fibro-cartilages, but it seems more probable that the actual starting-point is the adjacent synovial membrane or bone, with rapid invasion of the cartilage.

The symptoms and diagnosis have already been sufficiently discussed in a previous chapter (p. 348).

In the **Treatment** of a case of tuberculous disease of the knee, perfect rest of the joint from the earliest stage is essential; without this there is no hope of cure. If the knee is already flexed it may be necessary to overcome this gradually by a weight extension. Whatever kind of splint is applied it should extend from the fold of the nates to the toes, and during the first few weeks of the treatment the limb should be kept in a horizontal position. The splint may conveniently be made of leather or plaster of Paris. In applying plaster of Paris to such a case two long strips of household flannel should be cut sufficiently long to reach along the back of the limb from the fold of the nates to the heel and thence along the sole, and broad enough to extend two-thirds round the limb. The outer strip is completely soaked in thin plaster cream and the inner strip smeared with the cream on its outer surface only. The two strips are placed one on the other and quickly applied to the limb with a roller bandage. As soon as the acute symptoms have subsided, the patient may be allowed to get about with crutches, and wearing a patten or high-heeled boot on the sound foot so as to raise the foot of the affected limb from the ground. The most efficient apparatus at this time, and one which can be used from the first, is a Thomas's knee splint (Fig. 583). This has the additional advantage of leaving the joint exposed so that the effects of the treatment can be observed.

The apparatus consists of a well-padded iron ring, covered with leather, from which an iron rod extends downwards on each side of the leg, terminating in a second ring at the lower end. In ordinary cases in which the limb is tolerably straight the apparatus is thus applied:—The splint must be of such

a length as to extend from three to four inches beyond the foot. Two strips of strong strapping are prepared of sufficient length to reach from immediately below the head of the tibia to one inch beyond the sole of the foot; to one end of each of these a stout tape is firmly sewn. The strips are then applied to the sides of the leg, the tapes being below. To give additional security some narrower strips must be wound spirally round the leg, care being taken not to apply them circularly, or with sufficient tightness to constrict the limb. Over all, a flannel bandage may be applied from the ankle to the upper end of the tibia. The strips of plaster thus applied, if of proper quality, should retain their hold without shifting for many weeks. The limb is then passed through the upper ring of the splint, which is pushed upwards till it gets a

Fig. 583. — Thomas's Knee-Splint.

Fig. 584. — Thomas's Knee-Splint applied.

firm bearing against the tuberosity of the ischium. The splint is secured in position by tying the tapes attached to the strips of plaster to the ring at the bottom of the splint. It is not intended in so doing to extend the limb forcibly, but merely to retain the splint steadily in position. If the patient is to walk on the splint it is better to have a bar fixed between the two vertical rods, above their lower ends, to which the tapes can be made fast, otherwise they are quickly worn through. The limb being thus fixed longitudinally, lateral

and antero-posterior movements are prevented by two broad strips of plaster, about three feet long and three to five inches wide; one to be applied to the middle of the thigh, and the other to the leg opposite the calf. The strip of plaster is first fixed to one of the lateral rods, then brought over or under the limb, and back to the same bar, the remainder of the strip being wound round, including both bars and the limb. The second strip is then applied in the same way, but is fixed to the opposite lateral rod. A broad strip of plaster is next applied behind the knee between the two lateral rods, so as to support the ham. Lastly, a flannel bandage is smoothly applied from the toes to the groin. If properly put up the apparatus should not require changing for some weeks; the tapes must be tightened whenever they become loose, and the flannel bandage re-applied daily, but the strapping should not be touched. In walking, a patten is worn on the boot of the sound side, so as to equalize the length of the two limbs (Fig. 584). A broad strap may be carried from the splint over the opposite shoulder, as in Fig. 584, but if the strips of plaster are properly fixed to the leg, and the tapes tied sufficiently tightly, this is not necessary. A Thomas's splint applied as above described is perhaps the most perfect apparatus ever invented for fixing the knee. If, however, all the details are not attended to, it becomes as useless as any other form of splint. Even if the limb is flexed to a considerable angle, the Thomas's splint may be applied as above described, slight modifications being made to suit the altered position of the limb. After a few weeks in bed the limb will usually become straight, if no ankylosis exists.

During the time that the limb is on the splint the accessory means of treatment, such as counter-irritation or pressure by an elastic bandage, may be employed, should they be considered necessary; but in most cases simple rest is all that is required. If the joint improves under this treatment it must be patiently continued for many months, or even a year or more.

If, in spite of treatment by rest, the joint continues to enlarge, with increase of the pulpy swelling and perhaps signs of abscess formation, or should the joint be seen for the first time after these complications have arisen, operative interference is required. It is not necessary, however, to have immediate recourse to excision or amputation, if the general health of the patient is good and his surroundings are favourable. Simple incision of the joint, or **arthrotomy**, has been practised with success by H. O. Thomas and Rushton Parker. Free lateral incisions are made as far back as possible so as to drain the cavity thoroughly. If they are made too near the patella a pouch is left behind the incisions on each side, in which the discharges may accumulate. The incisions should extend from the level of the upper limit of the pouch of synovial membrane above the patella to the level of the tibia. If an abscess is burrowing beyond this point, the knife must be carried further, so as to lay it freely open. The incisions having been made, the pulpy granulation tissue filling the cavity of the joint may be freely scraped away with a sharp spoon, and if a carious patch be felt on either of the bones this also may be treated in the same way. In some cases sequestra may be found, and removed. The operation should be performed with the strictest antiseptic precautions. In the after-treatment drainage-tubes are not necessary if the incisions are sufficiently free. The dressing must be changed at the end of the first twenty-four hours, as it will be soaked by the abundant bloody and serous discharge which flows away immediately after the operation. An antiseptic cotton-wool

dressing, either of iodoform- or salicylic-wool may then be applied, enveloping the knee widely on each side, and surrounding the splint. This may be left undisturbed till some discharge soaks out, unless severe pain or elevation of temperature should indicate that all is not going on well. König strongly recommends the application of some iodoform to the inside of the joint at the operation.

Leaving out of consideration those cases in which amputation is required the Surgeon has, however, usually to choose between arthrectomy and excision. Although, in a few recorded cases, a movable joint has been obtained by arthrectomy when the disease has been still confined to the synovial membrane, this result can practically scarcely be anticipated, and as a general rule, an ankylosed joint in the extended position will be the most serviceable to the patient. This result can be obtained with greater certainty if sufficient of the articular surfaces of the femur and tibia is removed to allow flat bony surfaces to be brought into apposition. This has the additional advantage of removing any partially loosened cartilage and of bringing into view any tuberculous foci which may exist in the bone beneath it. The actual shortening of the limb which this procedure causes is too small to be a serious drawback, and it may therefore be laid down as a general rule that in adults the best results will be obtained by excision. In growing children, however, the case is different, for any removal of bone may seriously interfere with the subsequent growth of the limb, which, it will be remembered, depends so largely upon the epiphysial cartilages of the lower end of the femur and the upper end of the tibia. In children, therefore, formal excision has been largely replaced by arthrectomy, although there can be little doubt that the great advantage of unimpaired growth of the limb is obtained at a certain cost, for the complete removal of the disease is ensured with less certainty, and there is greater risk of an amount of subsequent mobility which too often leads to gradual flexion of the joint.

The ideal case for arthrectomy is one in which the patient is a child and the disease purely synovial. The principle involved is that only diseased tissues are sacrificed, and in many cases this necessitates removal of large portions of the articular cartilage and the thorough scraping of tuberculous foci in the bones.

In some cases, as the result of rest, the disease subsides in the greater part of the joint, and only in a certain portion progresses to a stage necessitating operation. Under these circumstances a limited operation only is required; this should consist in making a free incision into the affected part of the joint cavity and removing as completely as possible the tuberculous tissue.

**Arthrectomy of the Knee-Joint** was first performed in this country by Wright of Manchester in 1881, and has also been recommended by Ollier and Volkmann. It is thus performed:—The limb having been made bloodless by Esmarch's method, the cavity of the joint must be fully exposed. This may be done by a curved incision, extending from the posterior and upper part of the inner condyle to the corresponding point on the outer side, and extending downwards to a point about half an inch above the tubercle of the tibia. The ligamentum patellæ is then divided and the flap with the patella raised, fully opening the joint. Another method consists in making two lateral incisions extending on each side from the level of the upper part of the condyles of the

femur to the head of the tibia. These are connected by a transverse incision passing over the middle of the patella. The bone is then sawn through, and the flaps turned upwards and downwards. Other methods have been suggested, in which the patella and ligamentum patellæ are uninjured, but it is scarcely possible to expose the joint efficiently without dividing one or the other. The next step in the operation is thus described by Wright. It "consists in carefully cutting away with forceps and scalpel or scissors every particle of pulpy granulation tissue, all the infiltrated capsule and the semilunar cartilages, and scraping quite clean all the articular cartilages, picking out granulation tissue from any pits in the cartilage, and if necessary gouging away any small spots of diseased bone. The process must be thorough, and extreme flexion of the limb is required to completely expose and clean the posterior part of the joint; the crucial ligaments are scraped but carefully preserved, the lateral ligaments are usually divided. The upper synovial sac must be thoroughly cleaned. The most difficult part of the operation is getting away the posterior part of the semilunar cartilages and the synovial membrane at the back of the joint. The process is a tedious one, often lasting one and a half or two hours—including the subsequent putting up in a splint." Other Surgeons have divided the crucial ligaments in order to reach the back of the joint, subsequently uniting them by catgut sutures. When the operation is completed, if the open mouths of any vessels can be seen they may be secured with catgut ligatures. The wound may then be closed. If the ligamentum patellæ has been divided it must be united by thick catgut sutures. The patella, if sawn through, may be brought together in the same way, or silver wire may be used. It is very important to avoid the use of drainage-tubes. This may be done by making the incisions far enough towards the posterior part of the lateral aspect of the limb, and by sewing them up only in the middle, leaving at least two inches on each side to unite by granulation. An antiseptic dressing of some kind must then be applied. The following will be found very efficient. The wound is first dusted with iodoform; it is then covered with a strip of carbolized oiled silk to prevent scabbing; over this are placed four layers of carbolic gauze, wrung out of carbolic lotion, so that the early discharge may come directly in contact with a powerful chemical antiseptic during the first twenty-four hours. Over this again is placed a layer of iodoform or salicylic wool about one inch thick, and secured with an antiseptic bandage applied with moderate firmness. The Thomas's knee-splint can then be put on (p. 444). A large mass of salicylic wool many inches in thickness is next wrapped round the limb so as to include the splint, and to reach from the middle of the leg to the middle of the thigh, and over this a bandage is firmly applied so as to exert moderate elastic pressure. The limb is then elevated to a right angle and the tourniquet removed. If no bleeding occurs, the dressing may be left unchanged for a month or six weeks if the temperature remains low and no discharge appears. This mode of treatment has been adopted in a considerable number of cases in University College Hospital. In none has it been necessary to remove the dressing on account of hæmorrhage, and in the great majority the wound has been found healed or merely superficial at the first dressing a month or more after the operation. The essential conditions for success are: 1. Efficient antiseptic precautions; 2. Thorough removal of the diseased tissues; 3. Drainage without tubes by leaving some inches

of the wound open ; 4. The use of an efficient splint to ensure absolute rest ; and, 5. A lasting dressing. The Thomas's knee-splint should be worn continuously for a year after the operation, and after this it is generally advisable to apply a leathern splint for another year or more.

**Excision of the Knee-Joint** was originally performed at the close of the last century by Park, Filkin, and the Moreaus, but it fell into disfavour until it was revived in 1850 by Fergusson, since which time it has been extensively practised. As a means of treating tuberculous disease of the joint, excision has been much less frequently practised during the last few years, having been to a large extent replaced by arthrectomy. In growing children arthrectomy should, as a general rule, be the method adopted. After growth has ceased, arthrectomy has little advantage over excision, which for reasons already given (p. 431), may therefore be looked upon as the operation of choice.

It was at one time recommended that excision of the knee should not be undertaken after the age of 30, but that amputation should be performed. This rule must now be modified, and even in middle-aged patients, whose general condition is good, and in whom the local disease is not too extensive, excision may be given a trial : thus Gant has recorded cases successfully operated upon as late as 53. After middle age, however, tuberculous disease of the knee is usually an indication for amputation. Excision must also be abandoned in favour of amputation if there is very extensive bone disease, or infiltration of the soft parts, or if there is tuberculous disease of the lungs, or albumenoid degeneration of the viscera.

In neglected cases in which sinuses are present and deformity—usually flexion and displacement of the tibia backwards—exists, excision may be required before the faulty position can be remedied.

At the International Congress of 1881 Kocher of Berne maintained that in tuberculous disease, excision of the knee ensures a more rapid cure and a better limb than any conservative method of treatment, but this view is not generally accepted, although there is considerable difference of opinion on the matter. Thus, many Surgeons, whilst allowing that excision should only be employed among the upper and middle classes, and in country practice, when all other means have failed, have become so disheartened by repeated failures to cure white swelling of the knee in the children of the poor of large cities, that they have resorted to excision at a very early period. It is not wise, however, to adopt a uniform mode of treatment for all cases ; each should be dealt with on its own merits.

**The operation** may be performed by making a horse-shoe incision with

Fig. 585.—Elliptical Incision in Excision of the Knee-joint.

the convexity downwards, commencing at the side of one condyle of the femur, and passing immediately above the tubercle of the tibia to a corresponding point on the opposite condyle (Fig. 585). By this incision the ligamentum patellæ is divided, and the patella turned up in the elliptical flap; the crucial ligaments, if not already disorganized, are then to be cut across, any remaining lateral attachments divided, and the bones cleared for the saw. In doing this the limb must be forcibly flexed, and the knife carefully applied to the posterior part of the head of the tibia; for this purpose a blunt-pointed

Fig. 586.—Application of Butcher's Saw to Head of Tibia.

Fig. 587.—Lower End of Femur, excised.

Fig. 588.—Upper End of Tibia, excised.

resection-knife is the best. The articular surfaces must now be sawn off. This may be done with Butcher's saw; but in order to ensure a perfectly smooth section of the bones, it is better to use a common saw somewhat broader than that ordinarily employed in amputations. The lower end of the thigh-bone should first be removed. The saw-cut may safely be carried from before backwards, or in the opposite direction, as there is no danger of injuring the popliteal vessels. It must be made accurately at right angles to the shaft of the femur, in the antero-posterior direction; but, in the transverse, it should be parallel to the articular surface, that is to say, the inner side must be left slightly the longer, as the internal condyle is naturally longer than the outer. If the condyles retain their normal shape, it is not difficult to judge the proper angle at which the saw should be held; but if they are extensively and irregularly destroyed, the following guide may be taken. The patient lying flat on his back, the thigh is flexed to a right angle, and adducted till the inner side of the knee corresponds to the middle line of the body; the saw is then to be held parallel to the surface of the table. A thin slice is next taken off the tibia. It is usually recommended to cut from behind forwards (Fig. 586) to avoid wounding the popliteal vessels; but if ordinary care be taken there is no risk of doing this, and it is more convenient

to saw in the opposite direction. The section must be made accurately at right angles to the shaft of the tibia in both directions.

It has been recommended to saw the tibia concave and the femur convex, using a Butcher's saw, but it is difficult to do this so that the bones shall fit accurately, and the method presents no advantage over the ordinary way of operating. Care must be taken not to remove more of the bones than is absolutely necessary, especially in young subjects, lest the epiphyses be completely removed and the growth of the limb interfered with. It is usually sufficient to remove from one-third to three-fourths of an inch of the tibia, and about one inch or an inch and a half of the thigh-bone (Figs. 587 and 588). In young children the ends of the bones can sometimes be sliced off with a knife, and the amount taken away accurately limited to the diseased tissues. It not unfrequently happens that carious cavities are found extending beyond the level of the section that has been made ; when this is the case, it is better to apply the gouge to them than to saw the bone beyond their level. Should the operation be performed for deformity consequent upon badly reduced fractures or dislocations about the knee, as has been done successfully by Humphry of Cambridge, it may be necessary, in order to bring the limb into good position, to remove a wedge-shaped piece from one of the bones.

If the patella be much diseased, it must be removed ; if it be only slightly carious it may be scraped or gouged out ; and if healthy, in accordance with that principle of conservative surgery by which no sound part is removed, it should be left, becoming consolidated with and strengthening the joint. The articular surface for the patella on the thigh-bone, which extends some way up its fore part, may advantageously be sliced off, so as to leave an osseous surface, instead of a cartilaginous one, for the attachment of the patella.

I have always found the operation, as it has just been described, easy of performance and good in its results ; but various modifications are adopted by different Surgeons. Thus, some make one straight transverse incision ; others two parallel incisions, one on each side of the patella, or an H-shaped incision, and thus open the articulation from the side. Others advise that the patella be always removed. Volkmann recommends a straight incision from one condyle of the femur to the other across the middle of the patella, which is then sawn through, so as to expose the joint. After the articular ends of the femur and tibia have been removed, the fragments of the patella are united by sutures of catgut, carbolized silk or wire. If its articular surface is diseased it must be sliced off or scraped. The results obtained by this method are very good ; the patella readily unites by bone, and either remains movable or becomes fixed to the femur. The attachment of the quadriceps extensor and ligamentum patellæ being undisturbed, the tendency to displacement of the tibia backwards after the operation is counteracted, and in walking the action of the rectus in bringing the limb forwards is preserved.

After the ends of the bones have been removed, in cases of tuberculous disease, the pulpy synovial membrane must be cleaned away as completely as possible, partly by scraping with a sharp spoon and partly by the use of scissors and forceps. Some caution is necessary in cleaning the posterior part of the joint to avoid wounding the popliteal vessels. The healing of the wound is much facilitated and the chance of recurrence diminished by this proceeding. If sinuses existed before the operation, they may be scraped and cleaned with a solution of chloride of zinc.

In order to keep the bones in position some Surgeons recommend securing them with strong sutures of catgut or silver wire, whilst others prefer to peg them together. Marrant Baker uses two strong steel pins, which are passed obliquely through the skin into the tibia and are pushed on into the lower end of the femur. They are removed on the tenth or twelfth day. In most cases these special means of fixing the bones are unnecessary if an efficient splint is applied, but if the Surgeon prefer to use them he will find square ivory pegs useful. The bones are drilled obliquely, and after the pegs have been introduced the projecting ends may be cut off level with the surface of the bone.

It is very important that all hæmorrhage should be thoroughly arrested before the wound is closed. In some cases no ligatures will be required, but usually two or three of the articular arteries furnish sufficient hæmorrhage to require restraint. The flap when laid down will often appear inconveniently long and thick, but it must not be curtailed, as it will eventually contract and fit well. As a rule drainage-tubes are not necessary, and the flap having no tendency to become displaced, only requires a few sutures to hold it in position.

The result of the operation will depend mainly on the care taken in the after-treatment and in the successful prevention of decomposition in the discharges. It is essential for success that the limb should be kept at perfect rest for the first few weeks: any apparatus, therefore, which requires complete removal for dressing the wound should be avoided. A narrow splint of japanned iron extending from the buttock to the heel will usually answer the purpose sufficiently well. It must be padded where it is in contact with the thigh and the calf to such an extent that it does not touch the skin in the ham. It must be fixed in position by a flannel bandage above and below the knee, over which a firm plaster of Paris bandage must be applied. Heron Watson recommends a soft iron bar, applied anteriorly, reaching from the groin to the toes. The upper part is straight for the thigh; in the middle is an arch passing over the knee; the lower part is straight for the leg, and bent at an angle forwards opposite the ankle to fit the dorsum of the foot. At the lower end opposite the ankle is a hook by which the limb can be suspended. This splint, having been properly padded, is fixed in position with a plaster of Paris bandage. Thomas's splint will also be found a very efficient apparatus, and may be secured above and below the knee with a plaster of Paris bandage. By any of these means the limb may be immovably fixed, while the knee is sufficiently exposed to allow of dressing. Whatever apparatus is chosen, it must be applied while the patient is still under chloroform before leaving the operating table. As soon as the wound is healed, the limb may be completely encased in a plaster of Paris or starched bandage till the bones are firmly united to each other.

If proper attention be not paid to the position of the limb, bowing outwards is apt to take place. In order to prevent displacement, it has been proposed to divide the hamstring tendons: this, however, is never necessary.

The best dressing for an excision of the knee is that which requires changing least frequently, and most efficiently prevents decomposition of the discharges. That described as suitable to cases of erosion or arthrectomy (p. 448) can often be used with great advantage. Whatever dressing be used, the maintenance of perfect rest is absolutely essential. If this be attended to,

osseous ankylosis will ensue, and a good and useful straight limb will be obtained.

**Results of Excision.**—These have to be considered from two points of view : 1. The danger attending the operation, and 2. The utility of the limb left after it.

1. Statistics have been published in great abundance relative to excision of the knee, with the object partly of showing the absolute mortality and partly of contrasting excision with amputation. The general result of the older records was to show that about 30 per cent. of all excisions of the knee were fatal chiefly from septicæmia, pyæmia and exhaustion from prolonged suppuration, and that the mortality after amputation for disease of the knee was about the same. This heavy death-rate has, however, been greatly reduced, partly by the operation being undertaken at an earlier period, and not only as a last resource in order to save life, and partly by the modern improvements in the treatment of wounds. The following may be given as examples of later results. Kocher, an advocate of early antiseptic excision, in 1881, recorded 64 cases with 6 deaths, 3 from septic poisoning in the early days of the antiseptic treatment, 1 from hæmorrhage, 1 from carbolic acid poisoning, and 1 from acute tuberculosis. Messing, in order to illustrate the effects of the mode of dressing, collected 92 cases from the hospital at Kiel : 21 were performed before the introduction of the antiseptic treatment—of these, 7 died directly from the operation ; 23 were treated by antiseptic methods involving frequent change of dressing, and of these 2 died ; the remaining 48 cases were treated by the lasting antiseptic dressing, and of these only 1 died, from hæmophilia. Of the 92 cases, 14 underwent subsequent amputation. Sack of Dorpat, in 1880 published the results of 144 cases treated antiseptically by various Surgeons : of these, 25 or 17·3 per cent. died ; 4 from infective processes in the wound, 13 from tuberculosis and other general diseases existing before the operation, 1 from chloroform, and 1 from carbolic acid poisoning, 2 from causes unconnected with the operation, and 4 from causes not stated. Of the 119 who survived, 11 underwent subsequent amputation, making exactly 75 per cent. of successes and 25 per cent. of failures.

Howse published in 1892 the results of 130 excisions of the knee performed by him at Guy's Hospital and at the Evelina Hospital for Sick Children during the years 1873 to 1884. Of these cases only 6·2 per cent. died within six months after the operation, and of these only 4 deaths occurred during the first month and could be considered in any way directly due to the excision.

As in the present day amputation is performed only in those cases in which from visceral disease, extensive implication of the soft parts and bones or advanced age, excision is no longer practicable, no fair comparison can be made between the two operations as regards mortality.

2. The second point that has to be determined is as to the *Utility of the Limb* after the Operation.

On this point, the result of recorded cases is in favour of the operation. In one of Park's cases, operated on in 1783, that Surgeon states that the patient (a sailor), seven years after the operation, " was able to go aloft with considerable agility, and to perform all the duties of a seaman." In some of the later cases the result has been equally good. A boy, operated upon by Jones of Jersey, " could run and walk quickly without any aid of a stick, could stand

on the limb alone, and pironetted and hopped two or three yards without putting the sound limb to the ground." In several of my own cases an excellent, strong and straight limb has been left, useful for all ordinary purposes. In a case which I examined seven years after the operation, the limb was well nourished, straight, firmly ankylosed, and but very little shortened. The patient, a lad of twenty, could walk eight or ten miles, and even jump and stand on the limb without the least pain, sign of weakness, or difficulty. In very young children the result of the operation is not satisfactory, the leg continuing shortened and wasted, not developing with the rest of the body. This is apparently due to and dependent upon the removal of the epiphysis of the tibia, on the integrity of which the growth of that bone is dependent.

After the operation, osseous ankylosis takes place with a firm cicatrix; the limb is shortened from one to three inches, according to the amount of bone removed, but by means of a high-heeled shoe this inconvenience is to a great extent remedied. It has been urged against excision of the knee-joint, that convalescence is tedious and prolonged; but this argument can with justice have but little weight. If a useful limb can be preserved to the patient, it can matter but little if a few additional weeks be devoted to the procedure by which it is obtained: and, indeed, it is a question whether in many cases the patient may not be able to walk just as soon after excision of the knee-joint as after amputation of the thigh; for, as has been very properly remarked, though the amputation wound may be healed in three or four weeks, it may be as many months before an artificial limb can be worn.

Most valuable information as to the subsequent condition of the limb is obtained by a study of Howse's cases above referred to. "Of the 130 cases there were 65, or exactly 50 per cent., in which the results *are known* to be most satisfactory a long period (often many years) after the operation." In most of these the shortening was less than one inch, and the limb was straight or very slightly flexed; in 8 the shortening exceeded two inches, "but in every case the resulting limb was most serviceable, and far superior to a stump." Twenty-one cases were not traced, but the result was good when they left the hospital. In 12 cases the leg became flexed to a considerable angle. In 26 cases subsequent amputation was necessary, in two of them on account of albumenoid disease, which then gradually disappeared; in several of these the excision was done in advanced cases as an attempt to save the limb.

It is thus evident that by excision a firm, useful limb may be obtained in a large proportion of cases, and a similar record of cases treated by arthrectomy is needed before an accurate comparison of the two methods is possible.

#### DISEASES OF THE PATELLA.

Necrosis of the patella is rare. I have, however, met with two instances. In the case of an elderly woman, the necrosis came on without any evident external cause, commencing in the anterior part of the patella and gradually implicating the bone, until it became perforated, when rapid suppurative disorganization of the knee-joint ensued, necessitating amputation. The other case occurred after simple fracture of the patella, in a man, and is described in Vol. I., p. 632.

Tuberculous caries of the patella is the most rare of the different ways in which tuberculous disease of the knee-joint commences ; a chronic abscess slowly forms over the bone, and by early treatment the spread of the disease into the knee may be prevented. Sarcoma of the patella is very rarely met with. A specimen of round and spindle-celled sarcoma of the bone, for which amputation was performed by J. Lane, is preserved in the Museum of St. Mary's Hospital. In a case of pulsating myeloid sarcoma of the patella Lister removed the bone and obtained a useful limb by excising the articular surfaces of the femur and tibia.

## DISEASES OF THE TIBIA AND FIBULA.

The **Tibia** is very frequently the seat of tuberculous caries of the upper epiphysis, less frequently of the lower epiphysis. Chronic abscess is more

Fig. 589.—Limb with Necrosis of Fibula.

Fig. 590.—Limb after Removal of Fibula.

commonly met in the head of the tibia than in any other bone (p. 270). Necrosis of the shaft is usually the result of acute infective periostitis, but all the varieties of syphilitic disease are met with in this bone. The superficial position of its inner surface explains the frequency with which superficial necrosis results from chronic ulceration and other inflammatory affections of the parts covering it. Occasionally, as the result of acute necrosis, a considerable extent of the shaft, indeed the whole of it, may be removed as a loosened sequestrum, from the interior of the periosteum, more or less consolidated and strengthened by the deposit of new bone. Such operations present nothing special, and the result is usually very satisfactory, the limb that is left being strong, useful, and sound.

Disease of the **Fibula** requiring operative interference is rare, but necrosis may affect a part or the whole of the shaft. In one case, that of a child six years of age, I successfully removed the whole of the necrosed fibula. This operation is readily done by slitting up the sinuses in a direction so as to expose the sequestrum, which may then be drawn out without difficulty (Figs. 589 and 590). After the operation an inner splint must be applied, in

order to obviate the tendency to varus which will ensue. In the case from which the annexed drawings are taken, very considerable repair took place from the periosteum and soft tissues along the line of bone that had been removed; and the child, when examined two years after the operation, had an excellent, well-nourished, and useful limb. The foot, however, had a tendency to be drawn inwards, apparently owing to the flexors having overcome the antagonism of the peronei. This deviation inwards was counteracted by a properly constructed boot, with which walking was perfectly easy.

The commonest form of sarcoma of the tibia is a central myeloid sarcoma of the upper extremity; subperiosteal sarcoma is also more common in the upper part of the bone than the lower. Sarcoma of the fibula is rare, and usually attacks the upper end of the bone.

#### DISEASES OF THE ANKLE-JOINT.

The only affection of the ankle which needs special consideration here is **tuberculous disease**. In a considerable number of cases this begins after an injury and it has already been mentioned as an occasional sequela of a sprained ankle. The disease may be primarily synovial, or it may begin as a bone deposit, which, according to Watson Cheyne, is probably most common in the astragalus, but may occur in the upper part of either malleolus. The swelling, which is usually the earliest and most marked symptom of the disease, is generally most evident between the malleoli and the tendo Achillis; it fills the natural hollows around the joint and obscures the various tendons which pass in front of it. As in the case of the wrist, the tendon sheaths themselves may be diseased in association with, or independently of, disease of the joint itself.

Should suppuration occur the position of the abscesses varies much, but very frequently they come to the surface behind one or both malleoli. It is a point of great practical importance that neither the position of the swelling or abscess, nor the character of the impaired movement, may be sufficient to differentiate with certainty disease of the ankle-joint from disease of the tarsus not implicating the joint. In cases in which operation becomes necessary, the Surgeon should, therefore, make it his first endeavour to clear up this doubt by a careful exploratory incision and thus avoid the serious error of opening a healthy joint.

The **Treatment** of tuberculous disease of the ankle in its early stages should consist in fixing the joint at right angles with plaster of Paris, or with a leather or poroplastic splint. The patient may then be allowed to get about with the limb supported on a knee-rest. Operative interference is called for if the pulpy swelling increases and chronic abscess forms. In some cases good results have been obtained by freely opening and draining the abscesses antiseptically, still maintaining the joint at perfect rest. In cases in which this simple treatment has failed, or in which from the extent of the disease it is not practicable, the question arises: Can the Surgeon hope, by any conservative operation, to obtain a limb which will be more serviceable to the patient than the stump left by a Syme's amputation?

Formal excision of the ankle-joint has not, on the whole, yielded satisfactory results, and accordingly, considering the excellent results obtained by Syme's amputation, this has been extensively practised in stages of the

disease which in other joints would certainly be considered suitable for excision.

Of recent years, however, the operation of arthrectomy has been successfully extended to the ankle, and has been carried out on exactly the same lines as those laid down in the case of the knee-joint. The conformation of the ankle renders the complete removal of the tuberculous tissue more uncertain than in the knee, but the results so far obtained certainly justify a trial of arthrectomy in suitable cases—that is, in cases in which complete rest has failed to arrest the disease—Syme's amputation being reserved for advanced cases with extensive bone disease, and for those in which arthrectomy has failed. Amputation is also usually required when the disease occurs in persons past middle age.

**Arthrectomy of the Ankle** may be performed in various ways, and further experience of the operation is required before it is possible to decide which is the most generally useful. Clutton recommends the employment of four straight incisions, one in front of and one behind each malleolus, through each of which the diseased tissues are removed from the corresponding part of the joint. Cheyne has employed a longitudinal incision in front of each malleolus, and has divided the malleoli or removed the astragalus in order to gain free access to the joint. Arbuthnot Lane and others have freely opened the joint by a transverse anterior incision, the divided tendons being subsequently sutured. The lateral methods have the advantage of not dividing important structures. If the astragalus is at all extensively diseased it should be completely excised through an incision in front of the external malleolus. After the operation the foot should be kept fixed for a year and no attempt made at passive movement. Of 6 cases of tuberculous disease of the ankle in which arthrectomy was practised by Clutton, in 4 the result was very good, in 1 case there was slight displacement of the foot, but the patient was walking; the remaining case was not traced. In 5 cases treated by Cheyne, in which the astragalus was removed, a satisfactory movable joint was obtained.

**Excision of the Ankle** may be performed in the following way. The limb being placed on its inner side an incision is made commencing about two inches above the extremity of the outer malleolus, and following the posterior border of the bone to its tip. It is then curved round the malleolus and carried upwards in front of the bone to a point nearly opposite that at which it commenced. The incision must be carried firmly down to the bone, which is then cleaned by means of an elevator, the periosteum being carefully saved and the tendons of the peronei pushed backwards but not divided. The fibula is then cut through with a fine saw about half an inch above the level of the ankle-joint, and the malleolar portion is removed. The foot is now turned on the outer side and a similar incision made round the inner malleolus. Esmarch recommends that from the middle of the curve a vertical incision shall be carried up the tibia for about two inches, but this is not necessary if the original incision is of sufficient length. The malleolus and the lower end of the tibia are carefully cleaned with the periosteal elevator, the deltoid ligament being separated from the malleolus and the tendons raised and pushed on one side. The lower end of the tibia may be sawn across with a narrow saw and extracted from the inner wound. The saw may now be inserted again and the upper articular surface of the astragalus separated from

the rest of the bone. No important vessels or tendons should be divided in this operation.

It very rarely happens, however, that the disease of the astragalus is so limited as to make the operation practicable. When it is more deeply affected it may be removed piecemeal by the gouge, elevator, and bone-forceps, after which any disease of the articular surfaces of the calcaneum or scaphoid may be scraped away. After the operation the limb must be placed on a suitable splint (Fig. 591).

Excision of the ankle-joint has also been performed by a single incision on the outer side. If this plan be adopted the incision must follow the posterior border of the lower inch of the shaft of the fibula and the outer malleolus, round the tip of which it must be carried and then extended upwards and forwards, so as to give as much room as possible without dividing the extensor tendons. The lower end of the fibula is then removed, after which the astragalus may be loosened from its attachments or dug out with the gouge

Fig. 591.—Limb after Excision of the Ankle-Joint.

and the tibia afterwards exposed by dislocating the foot inwards. This operation is only applicable to those cases in which from the extent of the disease it is necessary to remove the whole astragalus. If it is intended only to cut away its upper articular surface the single incision does not give sufficiently free access to the joint.

From what has already been said it will be seen that in children formal excision of the ankle-joint may be replaced by arthrectomy, and that in adults it is doubtful whether, as a general rule, a more useful limb is not obtained by Syme's amputation. Excision for compound dislocations and fractures is now rarely performed, as in cases not requiring immediate amputation an attempt should be made to save the limb by more simple methods.

#### TUBERCULOUS DISEASE OF THE TARSUS AND METATARSUS.

Looking at this subject from a diagnostic point of view—and the treatment is most intimately connected with minute and accurate diagnosis—we find that the pathology of diseases of the tarsus is closely connected with its healthy anatomy. Composed of seven bones, it presents four distinct synovial

sacs—which have no communication with one another. These are well represented in the annexed diagram (Fig. 592). The *posterior calcaneo-astragalar* is the first of them ; next comes the (*a*) *anterior calcaneo-astragalar*, the synovial membrane here serving also for the *astragalo-scaphoid* ; the *calcaneo-cuboid* (*b*) is the third ; and the *anterior tarsal synovial membrane* (*c*) is the fourth and largest of all, and the most important from a surgical point of view. It extends between the scaphoid and the three cuneiform and the cuboid bones, between the two outer cuneiforms and the bases of the second and third metatarsal bones, and also between the external cuneiform and the cuboid. The articulation between the cuboid and the two outer metatarsal bones is shown at *d* ; and *e* is that between the internal cuneiform and the first metatarsal bone. These two (*d* and *e*) are not, strictly speaking, tarsal joints.

In the vast majority of cases, so far as my experience goes, it is the osseous structures, and not the articulations, which are primarily diseased ; but tuberculous disease, once set up in bones, speedily implicates the articulations secondarily.

Now it will easily be understood, on considering the arrangement of the tarsal synovial membranes, that the extent of disease will, in a great measure, depend upon its original seat. Thus, a person may have disease in the os calcis, extending even to the cuboid, with very little likelihood of its proceeding farther for a length of time. Such disease is limited to the outer part of the foot, does not involve its integrity, and can readily be removed by operation. If, however, the disease be in the scaphoid, or in one of the cuneiform bones, or in the bases of the second or third metatarsal bones, it will rapidly spread through the whole of the anterior and inner part of the tarsus.

When the foot is affected by tuberculous disease it becomes painful, the patient being unable to bear upon the toes or anterior ball of the foot. Swelling of a uniform character takes place, with tenderness at some point opposite the bones or articulations that are chiefly involved ; and eventually abscesses form, leaving sinuses through which the probe passes down upon softened and carious bone. These evidences of disease are usually most marked about the dorsum and sides, where the bones are superficial, the sole being often comparatively free—an important point in reference to operation.

The bones that are most frequently the seat of primary disease are the calcaneum, the astragalus, the scaphoid, the cuboid, and the metatarsal bone of the great toe.

In considering the *Treatment* of diseases of the bones and joints of the foot it is necessary in the first place to observe certain points in connexion with the construction of the part. In looking at the division of the foot into its three

Fig. 592.—Diagram of Synovial Membranes of the Foot.

component parts—toes, metatarsus, and tarsus,—we perceive that firmness of gait is given by the foot resting on the heel behind, and on the ball in front formed by the projection of the broad line of the metatarso-phalangeal articulations, more particularly that of the great toe; whilst elasticity is communicated to the tread by the play of the toes and metatarsal bones. The elasticity of the foot may be lost without any very serious inconvenience to the patient, but the preservation of stability is of essential importance; and as this is secured by the heel, the ball of the great toe, and the breadth of the anterior part of the foot, these are the most important parts to preserve in all resections of this part of the body.

In no region of the body have the good effects of modern conservative surgery been more distinctly shown than in the Tarsus. In the "good old times" of Surgery, if a person had a "white swelling" of the bones of the foot, he was at once condemned to amputation. Until a comparatively recent period, indeed, "diseased tarsus" was described as a whole. Surgeons did not endeavour to make out the exact extent and amount of the disease, and every case was looked upon as requiring amputation of the leg. The rule of practice then observed was, amongst the wealthier classes—those who could afford the expense of a "cork leg"—to amputate a little above the ankle; but, amongst the poorer classes, to remove the leg about a couple of inches below the knee, so as to give the patient a stump which, when bent, would fit into the socket of a wooden pin. Thus, in the latter case especially, not only was the sound leg sacrificed, but the patient was exposed to great additional danger; for the mortality after amputation increases, *ceteris paribus*, in exact proportion as we approach the trunk. This practice prevailed until Chopart drew some distinctions between the treatment to be pursued, according as the disease affected the anterior or the posterior tarsal bones and articulations. He showed that, when the anterior articulations only were affected, amputation at the junction of the astragalus and calcaneum with the scaphoid and cuboid—an operation which goes by the name of "Chopart's amputation"—ought to be performed; thus removing the whole of the disease, and allowing the patient to recover with a shortened foot, with the heel preserved—one on which he could bear the weight of his body, and which would be highly useful to him.

The next step in the conservative surgery of the lower extremity, in cases of diseased foot, was the operation introduced by Syme—that of disarticulation at the ankle-joint. This was certainly a great advance; for, the flap being taken from the heel, the patient has a stump on which he can bear firmly. The operation is also a very safe one. According to O. Weber, only 17 deaths occurred in 101 cases of this operation. I have performed it many times without a death.

With the introduction of anesthetics, Conservative Surgery made great strides; and I think Conservatism in Surgery may be regarded as the necessary result of Anæsthesia. For, although operations of this kind were performed years ago by Park, the Moreaus, and others, and their utility demonstrated, yet the operations of gouging, scraping, and partial resection were so painful and prolonged that patients dreaded to submit to, and Surgeons declined to undertake, them. Of late years Surgeons have learned to discriminate disease of one part of the tarsus from that of another, and to apply appropriate treatment to each.

In cases of limited tuberculous disease of the tarsus, especially in children, most excellent results are often obtained by scraping operations performed in the manner already described in the chapter on Diseases of Bones (p. 285). In this way formal excisions have been largely superseded and amputation avoided except in cases in which repeated recurrence and extension of the disease occur.

Primary disease of the articulations of the foot is a less frequent cause of operation than caries of the bones leading secondarily to an implication of the contiguous articulations; and the particular operation required will, in a great measure, depend upon the extent of implication of the synovial membranes of the foot. When the calcaneo-astragalar or the calcaneo-cuboid articulations are alone affected, with their contiguous bones, resection of the bones and joints implicated will often be attended with very satisfactory results; but when the large anterior tarsal synovial membrane is in a state of chronic disease, either primary or secondary to disease of the scaphoid, the cuneiform, or of either of the metatarsal bones connected with it, then resection is scarcely admissible, and Chopart's amputation offers the best means of relief. Inflammation of the large anterior tarsal synovial membrane commonly commences in disease of the scaphoid. It may, usually, be readily recognized in its earlier stages by the pain and swelling that take place across the line of articulation between the scaphoid and cuneiform bones, the pain being greatly increased by bending the foot down, and extending across the whole breadth of the foot. Although it is usually most severe at the inner side, which is the first affected, yet the external section of this complicated articulation—that between the external cuneiform and the cuboid—becoming involved, causes pain in the outer side of the foot as well. In the more advanced stages of this disease, the foot assumes a remarkable bulbous or clubbed appearance; the symmetry of the heel and the outline of the ankle are unimpaired, but the fore part and dorsum of the foot are greatly swollen, glazed and sometimes perforated by sinuses discharging thin pus. I look upon this disease of the anterior tarsal synovial membrane as a distinct affection of the foot, requiring to be diagnosed from the other strumous inflammations, and in its advanced stages calling for Chopart's amputation.

The **Os Calcis**, from its exposed situation, large size, and spongy structure, is more frequently the seat of caries and necrosis than any of the other tarsal bones. Very commonly the disease is limited to this bone; in other instances it extends into the calcaneo-astragalar or calcaneo-cuboid articulations.

When the *posterior or lateral part of the bone* is affected the neighbouring articulations are seldom involved, and then the removal of the disease by gouging or scraping with sharp spoons will usually effect a cure. I have frequently had occasion in this way to scoop out great portions, sometimes the whole of the interior of the calcaneum, with the most excellent

Fig. 593.—Disease of Os Calcis and Cuboid, and of Calcaneo-Cuboid Joint: Lines of Incision.

results. Even when the cuboid is extensively implicated as well, and the calcaneo-cuboid articulation is the seat of disease, the disorganized structures may often be removed by gouging and partial resection, as in the case of which Fig. 593 is a good representation, where, by means of a **I**-shaped incision, these bones were exposed, and their carious portions gouged out. Should, however, the caries have affected the *superior* or *anterior portions of the bone*, then the implication of the astragalar or cuboid articulations may render the excision of the whole bone necessary, as the only means of preventing extension of secondary mischief to the tarsus generally. So unfrequent, however, is disease of the articular aspects of this bone, that its complete removal is very seldom necessary, and out of at least fifty cases of caries of the os calcis that have been under my care, I have had occasion to excise the whole bone only once. The large size of the bone, its importance as a basis of support to the body and as the point of attachment of the strong muscles of the calf, should induce the Surgeon, whenever practicable, to avoid its complete extirpation, and to limit himself to the application of the gouge or sharp spoon, even though he may have to scoop out the whole of the interior of the bone, leaving little more than an osseous shell. This will fill up with dense fibroid tissue, which will probably eventually undergo partial ossification, and leave the foot as useful as ever.

**Excision of the Os Calcis** may readily be performed in the following way. The patient lying on his face, a horseshoe incision is carried from a little in front of the calcaneo-cuboid articulation round the heel, along the sides of the foot, to a corresponding point on the opposite side. The elliptical flap thus formed is dissected up, the knife being carried close to the bone, and the whole under surface of the os calcis thus exposed. A perpendicular incision, about two inches in length, is then made behind the heel in the mid-line and into the horizontal one. The tendo Achillis is next detached from its insertion with the periosteal elevator and the two lateral flaps are raised, if possible with the periosteum, by means of the elevator, aided if necessary by the knife (Fig. 594). The knife is then carried over the upper and posterior part of the os calcis, the articulation is opened, the interosseous ligaments are divided, and then, by a few touches with the point, the bone is detached from its connexions with the cuboid. This bone, together with the astragalus, must then be examined; and, if any disease be met with, the gouge should be applied. Should ankylosis have taken place between the os calcis and the astragalus, the bones may readily be divided by means of a saw. By this operation all injury to the sole is avoided; and the dependent angle of the wound affords good drainage.

The drawing (Fig. 595) gives an excellent representation of the state of the foot of a girl before and after the excision of a diseased os calcis—a somewhat flattened but most useful foot resulting.

**Ollier's Method.**—Ollier has described a mode of removing the os calcis somewhat different from the above. An incision, commencing on the outer side of the tendo Achillis, at least an inch above the level of the tip of the external malleolus, is carried down as far as the external tuberosity of the os calcis, and thence horizontally along the side of the foot as far as the base of the fifth metatarsal bone. The flap being raised, the periosteum and the tendo Achillis are separated from the bone, which is then further denuded of its periosteum as far as can be reached, the ligamentous attachments are divided, and the bone

is removed. In fact, in caries of the os calcis, it may often be found, as in performing Syme's amputation, that the thickened periosteum strips off the softened and carious bone as readily as the peel off an orange; hence a formal process of dissection is scarcely needed.

**History and Results.**—Excision of the os calcis is a very successful operation. It seems to have been first performed by Monteggia in 1813; the result appeared promising, when the patient died of scrofulous disease. The operation then fell into abeyance for twenty-four years, when Robert, in 1837, in a case of necrosis of the bone, removed the diseased portion, leaving the healthy peripheral layer. The same Surgeon, in 1844, in a case of caries,

Fig. 594.—Excision of the Os Calcis.

Fig. 595.—Disease of the Os Calcis.  
1. Foot before Operation : 2. Foot after Excision.

removed the whole bone with the exception of its upper articular surface and the inner side of the body. Greenhow of Newcastle, in this country, and Rigaud, in France, appear to have been the first Surgeons who successfully excised the whole of the os calcis. Their cases occurred in 1848; and since that time the operation has been performed in a large number of cases in this country and in America. In France, it seems to have met with little favour, though it has been successfully performed there in several instances, by Ollier, Giraldès, and some other Surgeons.

Polaillon, of Paris, in an able article written in 1869, with the object of advocating the performance of the operation, collected the records of 64 cases. Of these he set aside 9, of which he was not able to find sufficiently accurate statements as to the result. Of the remaining 55, 39 were successful—this

term implying that the patients were enabled afterwards to walk without artificial apparatus or support. Of the remaining 16, in 6, crutches or other apparatus were necessary; in 7, subsequent amputation was required on account of return of the disease or inutilty of the foot; and there were 3 deaths. Resection of the entire bone—in a few cases with other portions of the tarsus—appears to have been performed in 39 of the 55 cases: of these, 30 were altogether successful; in 4, artificial support was necessary; 2 required subsequent amputation, and 3 died. The operation, according to Polaillon, has been more successful in children than in adults. He states that, of 12 cases under 10 years old, all were successful; between the ages of 10 and 20, there were 14 successful cases, and 3 failures; between 20 and 30, 7 successes and 9 failures; and between 30 and 40, 6 successful cases and 3 failures. Reproduction of the bone occurred in 12 cases; 11 being in individuals under 20 years of age.

The **Astragalus** is situated in a position of great surgical importance. Articulating with the malleolar arch above, with the calcaneum below, and with the scaphoid in front—forming, as it were, the keystone of the foot—it is perfectly evident that any disease commencing in it is very likely to spread

Fig. 596. — Disease of Astragalus.

to and involve all the more important structures of the foot. Seldom indeed does disease originating in this bone long remain confined to it; and, so far as my experience goes, gouging operations, even if performed at an early period, are rarely of much benefit, the morbid process continuing to extend notwithstanding their employment. Indeed,

in diseased astragalus, I believe that excision ought, as a rule, to be practised in preference to gouging, contrary to what is the case in the calcaneum.

Disease primarily originating in the astragalus may spread in three directions: upwards into the ankle-joint, downwards to the calcaneum, forwards to the scaphoid, and thence through the large anterior synovial membrane to the rest of the tarsal bones. The treatment will vary according to the direction and extent of the disease. It may be arranged under four heads:—

1. When the *astragalus alone* is diseased we find what is seen in the drawing (Fig. 596), which represents the foot of a boy whose astragalus I excised—swelling just in front of the malleolar arch, with sinuses leading down to the diseased bone; the anterior part of the foot and the heel being quite sound. If the disease is limited to the outer side of the bone, or to its head, it is possible that, by freely opening the sinuses and applying the gouge, the caries may be entirely removed. But this operation is not so satisfactory here as elsewhere in the foot, as it is by no means easy to avoid opening the astragalo-scaphoid articulation; and if this be done, disease will probably extend through the tarsal articulations. Excision of the astragalus alone, though sometimes required for disease, is perhaps more frequently called for in those cases of compound dislocation in which the bone undergoes caries or necrosis.

The operation of excision of the whole of the astragalus for disease may be done as follows. A curved incision, from four to six inches in length, should be made immediately behind the outer malleolus, and carried forward on the outer part of the dorsum of the foot to opposite the fore part of the bone. The divisions of the external lateral ligament of the ankle-joint are then cut across, and the tendons of the peroneus brevis and tertius, and the extensor brevis digitorum muscle, divided. But the mass of extensor tendons in front of the foot, with the dorsalis pedis artery, must be left untouched. These should be drawn forcibly inwards. The peroneus longus tendon may be drawn backwards. The foot is then strongly twisted inwards, the astragalus cleared,

Fig. 597.—Excision of Astragalus. 1. Foot before Operation. 2. Foot six months after the Removal of the Malleolar Arch, the Astragalus, and a portion of the Upper Surface of the Calcaneum.

and its ligaments divided from the outer side in succession as they present themselves. When the operation is done for disease of the bone, these structures will usually be more or less softened and disorganized; when for injury, they will in a great measure have been torn through. Hence, in actual operation, the same steps cannot be followed so methodically as may be done on the dead subject. The bone must now be seized with lion-forceps and drawn well out of its bed; the knife being applied to any restraining structures, but being used very carefully towards the inner side of the bone, lest the plantar arteries be wounded. Under this process the carious bone usually breaks and has to be taken away piecemeal, or its neck may be cut across, and the head separately removed from its articulation with the scaphoid. If the bone have been dislocated, and its ligamentous connexions

thus torn through, or if these have been disorganized and softened by disease, it may readily enough be removed as just described; but if the osseous tissue itself be softened, and the ligamentous connexions tolerably sound, then the operation becomes extremely troublesome.

The result of this operation is very satisfactory; a good and movable articulation may be left between the malleoli and the calcaneum, and the limb is but little shortened. According to Hancock, of 109 cases in which the astragalus was removed, 76 recovered with good and useful limbs; secondary amputation was performed in two, with one death; 15 others died; and in 14 the results are not known. The operation was performed in 64 cases for compound dislocation, with 50 complete recoveries; in 20 of simple dislocation, with 14 complete recoveries; and in 10 for caries, perfect recovery taking place in 6.

2. When the disease has *extended from the astragalus into the ankle-joint*, the operative treatment must be carried out on the lines already considered at p. 457.

3. When the disease has *extended from the astragalus upwards into the malleolar arch, and downwards into the calcaneum*, the line of practice will depend on the extent to which the os calcis is implicated. If this be only partly involved, its upper surface only being affected, a great deal may be done by conservative surgery. The treatment in such cases consists, generally, in removing the astragalus from its bed, and gouging away any diseased bone which may exist either on the upper surface of the calcaneum or on the under surface of the malleolar arch. Very large portions of bone may be removed from this situation. I have taken away the whole of the malleolar arch and astragalus, and gouged out the upper surface of the os calcis very freely; and yet the patient has recovered with a strong and movable foot, but very little deformed.

The accompanying cuts (Fig. 597) were taken from a young man on whom I performed the operation just described. The foot was perfectly useful and strong, and the false joint at the ankle movable.

When extensive disease of the os calcis is associated with disease of the astragalus and ankle-joint, Syme's amputation is usually required, but if from the extensive destruction of the skin this operation is impracticable the only alternative to amputation in the leg is the osteoplastic resection described below.

4. If the disease have *extended from the astragalus to the scaphoid, and thence into the anterior range of tarsal joints*, the foot will have become so extensively disorganized, that partial resection will be of little or no service; and disarticulation at the ankle-joint should be practised.

**Osteoplastic Resection of the Foot.**—This operation, which was first performed by Wladimiroff of Kasan, and Mikulicz of Prague, has been practised and especially advocated in this country by MacCormac. It is available for cases of disease of the ankle, astragalus, and calcaneum in which the soft parts in the neighbourhood of the heel are extensively destroyed, as well as for cases of severe injury of the same parts. The operation is thus described by MacCormac. The patient being placed in the prone position, a transverse incision is made across the sole of the foot from a point just in front of the tubercle of the scaphoid to a point behind the tuberosity of the fifth metatarsal bone. From each extremity of this incision another is carried obliquely upwards and backwards over the corresponding malleolus, and these are joined

by a transverse one across the back of the leg. This last incision is made down to the tibia just above the level of its articular surface.

The ankle-joint is then opened from behind and disarticulated. The foot is now dorsally flexed and the soft parts carefully separated from the bones until the mid-tarsal joint is reached and disarticulated. The astragalus, os calcis, and the soft parts of the heel are thus removed. The malleoli and the articular surface of the tibia are then sawn off from behind forwards, and the surfaces of the scaphoid and cuboid similarly treated. The anterior part of the foot is left attached by the soft parts and tendons lying in front of the ankle. Finally, the sawn surfaces of the scaphoid and cuboid are sutured to those of the tibia and fibula, thus bringing the remains of the foot into a line with the leg. MacCormac has recorded two cases in which he performed this operation with satisfactory results, in one for tuberculous disease of the os calcis and astragalus

Fig. 598.—Tuberculous Disease of the Scaphoid, spreading to other bones through the anterior tarsal synovial sac.

Fig. 599.—Disease of Cuneiform Bones.

and the soft parts over them, and in the other for extensive sloughing of the heel following an injury. After the operation the patient walks on the ends of the metatarsal bones with the toes bent forwards at a right angle.

Excision of the **Cuboid Bone**, either in whole or in part, may be required. Partial excision is here done with the gouge. When the whole of the bone is taken away, the fifth metatarsal bone also, with the little toe, will probably require removal. This may be done by making the flap, as depicted in Fig. 55, Vol. I., only commencing the incision about an inch further back, opposite the calcaneo-cuboid articulation, and opening this instead of the metatarso-cuboid.

The **Scaphoid Bone** is very commonly the seat of primary disease; and,

as this bone is connected in front with the large tarsal synovial membrane, and posteriorly with that which is common to the calcaneo-astragalar and astragalo-scaphoid articulations, the greater part of the tarsus is apt to become speedily involved (Fig. 598). The extent of this implication is such, that excision of the primarily diseased bone would probably seldom be attended with much benefit, and Chopart's amputation or disarticulation at the ankle-joint becomes necessary. Next to disease of the astragalus, I look upon tuberculous inflammation and caries of the scaphoid as most destructive to the integrity of the foot.

When the **Cuneiform Bones** are the seat of caries, it will generally be found that the middle is the bone primarily affected. Thence the disease extends to the lateral ones, or to the bases of the second and third metatarsal bones (Fig. 599). In such cases the anterior tarsal synovial membrane usually becomes extensively implicated, and Chopart's amputation will be required. But if the disease continue to be limited to the middle cuneiform and the contiguous metatarsal bones, and the patient's general health be good, removal of the affected osseous structures by the gouge, with extraction of the carious cuneiform, may be attended with satisfactory results.

**Excision of more than one of the Tarsal Bones** is sometimes required in chronic disease, and may leave an excellent limb. No formal rules for the operation can be laid down; the course of proceeding must depend on the nature of the case and the judgment of the Surgeon. In a lad who was many years since under my care with very extensive disease of these parts, I removed the lower three inches of the fibula, and gouged away considerable portions of the end of the tibia and of the astragalus, calcaneum, and cuboid—removing a whole handful of carious bone; yet a perfect cure resulted, the patient recovering with a strong and useful foot. The os calcis with the astragalus was successfully removed by T. Wakley in 1848, and by Watson of Edinburgh; and the os calcis, almost the whole astragalus, and a part of the scaphoid, by Nicholls of Chelmsford. Mulvany, in a case of disease of the tarsus consequent on compound dislocation, removed the greater part of the scaphoid, half the os calcis, all the astragalus, and the lower end of the tibia. Fayrer removed the articular ends of the tibia and fibula, the os calcis, astragalus, and scaphoid for disease, in a boy 9 years old; and Lehmann of Polzin, in a case of caries in a man aged 40, removed by subperiosteal excision the entire os calcis, the astragalus, and the scaphoid bones, the foot having a perfectly normal appearance three months after the operation, and the patient being able to walk well, without a stick.

In infants and very young children, disease of the tarsal articulations and even bones may often be recovered from, without the necessity of having recourse to operation, by attention to the child's general health, and by giving the part rest.

In cases of disease of the **Metatarsal Bones**, treatment by scraping is often successful, but amputation is not uncommonly required. This is more particularly the case with the first and the fifth (Vol. I., p. 114).

The middle metatarsal bones cannot advantageously be taken away, leaving merely the first and last; but the two, three, or even the whole four of the external metatarsal bones may be resected in early life, and a useful foot left. Aston Key has recorded a case in which, in consequence of injury, he removed the four outer metatarsal bones, the cuboid, and the external and middle

cuneiform, leaving merely the line of bones supporting the great toe, but a very good foot resulted, by which the patient retained in a great measure his elasticity of tread.

For tuberculous disease of the **Phalanges** amputation is usually required. In the case of the great toe, no more of it should be removed than is absolutely necessary, as it enters largely into the formation of the arch of the foot. It is especially of importance that the ball of the great toe, if possible, be preserved; and occasionally this may be effected by excision of the metatarso-phalangeal articulation rather than by the amputation of the member. With regard to the removal of the toe and its metatarsal bone, I must refer to Vol. I., p. 114. Whenever it is practicable, the proximal end of the bone should be saved, in order that the insertion of the tendon of the peroneus longus may be preserved.

## CHAPTER LI.

## DISEASES OF THE SPINE.

**SPINA BIFIDA.**

**SPINA BIFIDA** is a congenital malformation of the vertebræ in which there is an incomplete development of a certain number of the neural arches. Through the cleft thus left the contents of the spinal canal protrude, forming a tumour of variable size projecting in the middle line of the back. In extremely rare cases a cleft condition of the bodies has been met with, the tumour then projecting forwards into the thorax, pelvis, or abdomen. Such cases are merely pathological curiosities, and cannot be recognized during life. Our knowledge of the pathology and treatment of spina bifida has been greatly increased by the report published in 1885 by a Committee of the Clinical Society of London. It is by no means an uncommon malformation, for in 1882, 647 deaths occurred in consequence of it in England alone.

**Symptoms.**—The tumour in spina bifida is usually oval, its long diameter corresponding to the axis of the spine. It is most often sessile, but occasionally, when the cleft implicates only a few neural arches, it is pedunculated. In size it commonly varies from that of a walnut to that of an orange, but in rare cases it may equal or even exceed that of a foetal head. Very frequently the tumour presents a longitudinal furrow, with a depression indicating the point at which the protruded cord is in contact with the sac. In some cases it is lobulated, having an imperfect septum stretching across it. In a few recorded cases more than one tumour has been present. The skin covering it is in rare cases normal throughout; but far more commonly the natural integument surrounds the base only, the central parts of the tumour being covered by a thin glistening bluish-white membrane, presenting a certain degree of translucency. The central part usually becomes congested or inflamed from friction of the clothes and the irritation of urine, and as the tumour increases ulceration commonly takes place; this may end in perforation of the sac, which is almost inevitably followed by septic spinal meningitis and death. On examining the tumour it will be found to be tense though elastic when the child is held in the upright position, and to diminish when the child is laid flat on its face. It becomes more tense during forced expiration, as during crying, and less so during inspiration. Fluctuation is usually very evident, and in some cases the bulk of the tumour may be distinctly lessened by steady pressure, while at the same time increased tension may be recognized at the anterior fontanelle, thus demonstrating the connexion of the sac with the subarachnoid space. Manipulation is not usually painful unless the skin is ulcerated.

Spina bifida may be met with in any portion of the vertebral column; but by far the most frequent situation is the lumbo-sacral region, which is the part of the spinal canal which closes last in foetal life. Over 50 per cent. of

all cases are met with in this part. Next in frequency stands the sacral region, with about 17 per cent. The remaining 33 per cent. are scattered about equally over the other portions of the spinal column.

Spina bifida is not uncommonly associated with other deformities, especially club-foot, talipes calcaneus being a common form. Hydrocephalus is also a frequent complication, and paralysis of the parts below the tumour is often met with. In 245 cases collected by the Committee of the Clinical Society, paralysis was recorded as being present in 53, talipes in 42, and hydrocephalus in 30. Ulceration of the lower limbs, apparently trophic in nature, has also been observed. The malformation is slightly more frequent in females than in males.

**Pathological Anatomy.**—The tumour in spina bifida is described as being composed of a sac with its coverings and contents. The sac consists of the membranes of the cord protruding through a gap left by the want of union of some of the neural arches; the coverings are the integuments of the back, and the contents are cerebro-spinal fluid in all cases, and in a large proportion a portion of the cord and the nerves proceeding from it. The cerebro-spinal fluid is clear and limpid in appearance, and of a specific gravity of from 1003 to 1006. It contains merely a trace of albumen, a considerable amount of chloride of sodium, and a trace of a substance which, like sugar, reduces copper salts. In some forms the sac, its coverings and its nervous contents, are quite distinct; but more commonly the integuments, the protruded membranes and the projecting portion of the cord, are blended together at the most prominent part of the tumour.

There are three chief forms of spina bifida :—

1. **Spinal Meningocele.**—In this form the membranes only are protruded, the cord and nerves retaining their normal position. Of the 125 cases examined by the Committee of the Clinical Society, 10 were of this variety. The tumour is commonly pedunculated, and escapes by a small cleft left by the want of union of one or two neural arches at the most. It has even been known to protrude between two normal neural arches. The skin covering it may be normal, but more commonly it is scar-like in the central part. Simple meningocele may occur at any part of the spinal column. It may protrude from the natural cleft at the lower end of the sacrum, forming one variety of the so-called “congenital sacral tumours.” Patients affected with this form may live to adult life, the tumour ceasing to increase at a comparatively early period, and possibly undergoing spontaneous cure, but this fortunate result is exceptional. In the museum of University College is a specimen obtained from a woman aged 32, who died from other causes. The tumour is covered by healthy skin and a dense fascia. It is composed of three sacs, separated from one another by membranous septa, and only one of these, and that the smallest, communicates with the spinal canal.

2. **Meningo-myelocele.**—In this form a portion of the cord and the nerves coming from it are protruded with the membranes. Seventy-six of the 125 cases examined by the Committee were of this kind. The tumour is very commonly sessile, and corresponds to a cleft formed by the want of union of several neural arches. The wall of the protrusion, except in its central part, will be found to be composed of normal skin, dura mater, and arachnoid, each of which can be recognized. The central part is scar-like in appearance, and composed of a layer of epithelium covering a thin layer of

fibrous tissue, representing the cutis and the protruded membranes, with the inner surface of which the projecting part of the cord is incorporated. The sac is distended with cerebro-spinal fluid, and the nerves arising from the protruded part of the cord cross the cavity to reach their respective foramina

(Fig. 600). The nervous tissue of the cord is usually much thinned and spread out at the point at which it is adherent to the sac, so as sometimes to be scarcely recognizable except by the nerves springing from it. In most cases a shallow depression marks externally the point at which the cord is adherent to the sac.

Fig. 600.—Meningo-myelocoele in vertical section.

3. **Syringo-myelocoele.**—In this form the central canal of the cord is dilated, and the interior of the sac formed by the protruded membranes is lined by a thin layer of nervous tissue, between which and the sac lie the nerves arising from the part of the cord implicated. This variety is very rare. The Committee of the Clinical Society met with only two unequivocal examples.

Under the name of **Spina Bifida Occulta** a few cases have been described by Ornstein, Virchow, Fischer, Recklinghausen, Bland Sutton and others, in which the essential conditions of a meningo-

myelocoele are present without the protrusion of any tumour. That is to say the neural arches are cleft, and in the gap the skin, membranes and cord are blended together. There is a depression corresponding to the deficient spine, and from this has sprung in all recorded cases a tuft of hair, sometimes of extraordinary length. In some of the cases the whole lumbar region was covered with thick hair. This form of the disease has been accompanied in several of the recorded cases by ulceration and disease of the bones of the foot, resembling the so-called "perforating ulcer" (p. 19), and a case of the same kind was recently in University College Hospital. In a case of this nature in which amputation of the foot was performed, Klebs found well-marked inflammation of the nerves. In some cases there has been a slight degree of club-foot, and in some instances extroversion of the bladder.

In another rare form of spina bifida occurring in the sacral region, the tumour is composed of a small protrusion of the membranes covered by a thick layer of somewhat dense fat, completely concealing the nature of the disease. I have known of a case in which an attempt was made to remove the tumour, under the impression that it was a fatty outgrowth. The small protrusion of the membranes was only discovered when it was wounded towards the end of the operation. The patient died of septic spinal meningitis.

The occurrence of spina bifida has been attributed to an excessive secretion of cerebro-spinal fluid, or to dropsy of the central canal, causing a protrusion of the membranes, and thus preventing the union of the neural

arches. Possibly in the case of a simple meningocele the former may be the true explanation. In the meningo-myelocele, however, as pointed out by R. W. Parker and Shattock, this theory will not explain the displacement backwards of the cord and its fusion with the thin central part of the sac. In these cases it is apparently due to a primary arrest of development of the neural arches occurring at a very early period immediately after the separation of the part of the epiblast forming the spinal cord from that forming the epithelial covering of the body. Normally this should be followed by the development of two processes of the mesoblast, one from each side, which insinuating themselves between the epithelium and the primitive spinal cord, subsequently develop into the neural arches and membranes of the cord. An arrest of the development of these processes explains the pathological appearances in this form of spina bifida.

The **Diagnosis** of the different forms is in many cases impossible. When the tumour is pedunculated and covered by healthy skin, it is probably a simple meningocele. When it is sessile, covered in great part by thin, almost translucent, scar-like tissue, and presents a furrow or depression in the middle line, it is almost certainly a meningo-myelocele. The syringo-myelocele cannot be recognized with certainty.

The **Prognosis** is always bad. Spontaneous cure does, however, occasionally take place, 14 such cases having been collected by the Committee of the Clinical Society; but these form a small percentage of the whole. A simple meningocele is not incompatible with long life if it is pedunculated and covered with healthy skin. The meningo-myelocele is commonly fatal if not relieved by treatment, death usually occurring from convulsions, or from ulceration and perforation of the sac and septic meningitis. The syringo-myelocele is probably inevitably fatal. The larger the tumour in all forms the worse is the prognosis. It may be stated as a general rule, that spina bifida is more dangerous the higher it is seated on the spine. Paralysis of the parts below the deformity is a hopeless complication.

**Treatment.**—In cases in which the infant is otherwise healthy, the tumour small, pedunculated, and covered by healthy skin, and showing little or no tendency to increase, we shall probably best consult the welfare of the child by abstaining from all operative interference, and merely protecting the tumour by a piece of leather or cotton-wool. On the other hand, if the tumour is increasing in size, there is little hope of recovery without operative interference. According to the Committee of the Clinical Society, the best results are to be hoped for in children who have reached the age of two months, in whom there is no paralysis or hydrocephalus, and when the sac is covered by healthy skin. Distinct evidence of the cord being in the sac, as shown by umbilication and a longitudinal furrow; a very thin membranous or ulcerated sac; previous rupture; the occurrence of a distinct impulse between the sac and the anterior fontanelle; a sac, the contents of which are easily returned into the spinal canal, and a very early age of the patient are all unfavourable conditions, yet do not necessarily contra-indicate operation if the general health is good. If the child is wasted, hydrocephalic, or paralysed below the tumour, any surgical interference will probably only hasten the inevitable death.

Six methods of treatment have been adopted for the cure of spina bifida: puncture or aspiration followed by pressure; ligature of the neck of the sac;

excision of the sac; antiseptic drainage; injection of tincture of iodine, and injection of Morton's iodo-glycerine solution.

Puncture is not a very successful mode of treatment, being very commonly fatal by meningitis. Of 46 cases treated in this way, collected by the Committee of the Clinical Society, 30 died. The case from which the accompanying drawing (Fig. 601) is taken, was, however, cured by this treatment. It was that of a young girl. At birth the tumour was small, but it gradually increased in size, until when the child was thirteen it had attained the following dimensions:—Circumference at base 25 inches; length over greatest convexity 19 inches; breadth  $14\frac{1}{2}$  inches. The tumour occupied the lumbo-sacral, and stretched over both gluteal regions. It was tense and translucent; the skin reddened, very thin, and becoming darkly congested at the more prominent part, evidently in imminent danger of bursting. Health excellent; develop-

Fig. 601.—Large Spina Bifida, cured by tapping and pressure.

ment good. I tapped the tumour and drew off 101 ounces of cerebro-spinal fluid. When emptied, an aperture  $1\frac{1}{2}$  inch long, and three-quarters of an inch broad, could be felt at the lower lumbar and upper sacral regions to the left of the mesial line. The parts were well padded with cotton-wool, and supported by an elastic bandage. No ill effects followed the tapping. This was repeated nine times in eighteen weeks, 985 ounces in all of clear cerebro-spinal fluid being drawn off; the largest tapping amounted to 120 ounces, the smallest to 23. After each tapping methodical compression was employed. The ninth tapping was followed by signs of irritation in the lining membrane of the tumour, which became greatly thickened, evidently by inflammatory exudation. The temperature rose to  $103^{\circ}$  F., and symptoms of spinal meningitis with a tendency to opisthotonos and convulsive movements came on, but passed off. The sac gave

way and a considerable quantity of pus was discharged, after which all the symptoms were relieved. The cavity closed by granulation, the skin covering it being thickened and corrugated; the patient soon completely recovered, and fifteen years after the operation was strong, healthy, and active.

By the combination of pressure and occasional tapping by means of a trochar, Astley Cooper succeeded in curing one case. If it be thought desirable to apply pressure it may be done by means of a compress and bandage; or, what is better, an air-pad, similar to those used for umbilical hernia, kept in place by an india-rubber band. Any punctures made in tapping must be carefully closed with collodion.

Removal of the tumour by **ligature** or **gradual strangulation** is evidently justifiable only in cases of simple meningocele, and even in these it has not been attended with any great degree of success. Wilson in one case removed the tumour by the gradual pressure of a clamp applied to its base, and keeping the parts in close apposition by means of this instrument, so as to prevent the entrance of air, and the consequent occurrence of septic meningitis. In this case the tumour was as large as an orange, and not

pedunculated. If it have a narrow base, the prospect of cure by this means will be better, but before attempting any operation of this kind the tumour should be illuminated by strong transmitted light in order to ascertain the presence or absence of the spinal cord or nerves.

**Excision** is open to the same objections as ligature. In fact, all plans of treatment, by which the tumour is opened, and the air allowed to enter it, are fraught with danger from inflammation of the meninges of the cord and convulsions, and, as a general rule, are to be condemned. Simple meningocele has been successfully treated by antiseptic drainage and by complete excision of the sac with antiseptic precautions. Of recent years also many attempts have been made, and in some instances with success, to treat meningo-myelocele by excision of the sac after separating and reducing the median portion with which the cord is blended. It is doubtful, however, whether the amount of success which has followed these operations justifies their repetition.

The Committee of the Clinical Society, after a most exhaustive inquiry, report strongly in favour of **injection of the sac** as the most efficient mode of treatment. They record 26 cases in which aqueous or spirituous solutions of iodine were used, with 20 recoveries, 5 deaths, and 1 failure. These were probably carefully selected, and show a higher rate of success than could be expected if the treatment were more widely adopted. The simple iodine solutions have been almost completely abandoned since 1876 in favour of a special preparation introduced by Morton of Glasgow. It is composed of iodine gr. x., iodide of potassium gr. xxx., and glycerine ʒj. The advantage of the glycerine solution seems to be that it diffuses extremely slowly, and consequently if the patient be kept recumbent and partially erect, it has little tendency to extend into the spinal canal. The quantity injected should be from half a drachm to a drachm and a half. The injection is best done by means of a screw syringe fitted with a fine platinum needle. If the sac be tense, the needle may first be introduced and a small quantity of the fluid drawn off, but in most cases the iodo-glycerine solution may be directly injected. The puncture, which should be made through the thick part of the coverings at the lateral aspect of the tumour, must be carefully closed with lint and collodion. Should the sac continue to leak at the puncture, suppuration and meningitis are very likely to occur. After the injection a flannel bandage may be applied over some cotton-wool covering the tumour, and the child must be kept as far as possible in the recumbent position. The Committee have collected 71 cases treated by this method, of which 35 recovered, 27 died, 5 were unrelieved, and 4 were improved. Since the publication of Morton's paper in 1877 his treatment has been very widely adopted, perhaps without sufficient care in the selection of proper cases. Amongst the 71 cases no fewer than 22 were suffering from paralysis, and only 17 are stated to have been free from complications. Moreover, in many of the fatal cases, death was not due directly to the treatment. Morton himself in 1885 stated that he was able to refer to 50 cases, 41 of which might be regarded as successful. It is evident, therefore, that when we consider the dangers accompanying other modes of treatment and the hopelessness of the disease in most cases if left to itself, the amount of success obtained is quite sufficient to justify the injection of the iodo-glycerine solution in all cases not evidently unsuited for any operative interference.

In a few recorded cases the spontaneous cure of a spina bifida has been followed after a varying interval by paralytic and trophic phenomena. A remarkable case of this kind has been recorded by Jones of Manchester; the symptoms, which consisted of incomplete paralysis and anæsthesia of the lower limbs, and perforating ulcers of the feet, developed at the age of seventeen years. Operation was undertaken at the age of twenty-two, and a fibrous band compressing the cauda equina was divided; great improvement followed.

TUBERCULOUS DISEASE OF THE SPINE.—CARIES OF THE SPINE.—  
ANGULAR CURVATURE.—POTT'S DISEASE.

This disease, which was first accurately described in 1779 by Percival Pott, the celebrated surgeon to St. Bartholomew's Hospital, consists, in its full development, of destruction of the bodies of some of the vertebrae, with disintegration of the corresponding intervertebral fibro-cartilages. It most commonly occurs in young children, sometimes even during the first year of life. It is, however, met with at later periods, not uncommonly commencing at puberty, and sometimes even late in life. I have seen it set in after fifty.

**Causes.**—It is now universally recognized that the commonest, if not the only, cause of the destructive inflammation of the vertebrae which is the essential element of this disease, is a deposit of *tubercle* in the bones of the affected part. In many cases undoubtedly the first symptoms of the disease follow some *injury* to the spine, such as a fall, and it is an important fact that a very common starting-point is the soft growing tissue between the bone and the epiphysal layer of cartilage, especially at the anterior part which would be most powerfully compressed during forcible flexion of the spine. It is indeed conceivable that the traumatic inflammation of the bone, which under favourable circumstances would rapidly subside, may, as the result of want of rest and constant pressure on the part, especially if occurring in an unhealthy subject, give rise to a chronic rarefying osteitis, ending in more or less extensive destruction of the bodies of the vertebrae. In these cases, therefore, which distinctly follow an injury, and which recover without supuration, it is not possible to prove their tuberculous nature. It is, however, far more probable that the persistence of the inflammation, resulting in the first place from the injury, is due to a deposit of tubercle in the damaged area, and the existence of a simple non-tuberculous caries of the vertebrae must be considered doubtful.

The evidence in proof of the tuberculous nature of at least the majority of cases is as follows:—First, the disease frequently commences in many independent centres, often in the bodies of different vertebrae, and in situations, such as the front of a body or in its central parts, which are little exposed to injury. Secondly, in patients dying of advanced caries affecting one part of the spine, separate centres of disease in an earlier stage are frequently found in other vertebrae. The granulation tissue removed from these has been shown to contain non-vascular, caseating nodules presenting the characteristic anatomical structure of tuberculous tissue (Vol. I., p. 1086), and further the presence of the tubercle bacillus has been demonstrated in many cases. Thirdly, the early caseation of the inflammatory products and the chronic

suppuration, correspond with the course followed in tuberculous inflammations elsewhere. And, lastly, a considerable proportion of patients dying of caries of the spine are found to be affected with general tuberculosis.

**Pathology.**—Leaving out of consideration those rare instances in which the spines or transverse processes of the vertebræ are primarily affected, we have to consider the relative frequency with which the disease commences in the bodies and in the intervertebral fibro-cartilages. This has been a subject of considerable difference of opinion, some Surgeons maintaining that in the great majority of cases the intervertebral cartilage is the starting-point of the destructive process, and others that this is rarely, if ever, primarily affected. The cause of this uncertainty seems to be that by the time the opportunity arrives for examining the diseased structures the morbid changes are so advanced that it is impossible to say where they commenced. In the vast majority, if not in all, of the specimens obtained at an early stage of the disease, from patients dying of some accidental complication, there is no doubt that the starting-point of the morbid change is the bone. While, therefore, we are not in a position to deny that the disease may originate in the intervertebral discs, this mode of origin is, to say the least, rare.

In connexion with the bodies of the vertebræ tuberculous disease may commence superficially beneath the periosteum, or in the cancellous tissue of the bone, either centrally or beneath the epiphysial cartilage on the upper or lower surface. The pathological processes occurring in caries of the vertebræ differ in no material respect from those already described (p. 265) as taking place in tuberculous disease of bone elsewhere. When it commences in the cancellous bone, the vessels of the medullary tissue are first dilated in the affected area (inflammatory congestion); the tissue next becomes infiltrated with small round cells before which the normal structures disappear. Thus the cancellous spaces become filled with new cells, amongst which capillary loops may penetrate (granulation tissue). The bony trabeculæ enclosing the spaces are first thinned and finally completely absorbed by the advancing cell-growth; thus a portion of the cancellous tissue of the body of a vertebra may be destroyed, its place being occupied by granulation tissue. These changes form an essential part of all varieties of caries; the fate of the granulation tissue, however, differs in different cases, the following being the chief modifications of the subsequent processes:—

1. The granulation tissue replacing the cancellous bone may be absorbed apparently as the result of the pressure exerted upon it by the weight of the trunk. Thus a steadily progressive destruction of bone may take place without there being any extensive accumulation of granulation tissue, and without the formation of pus. This *dry caries*, as it is termed, is very common in the spine, being the process that takes place in those numerous cases of angular curvature in which the patient escapes without the formation of an abscess. Its progress is sometimes very rapid, leading to great deformity in a very short time.

2. Instead of being absorbed the granulation tissue may undergo fatty degeneration, and a slow process of *suppuration*, with the formation of curdy pus, may take place. The pus gradually accumulates, forming a chronic abscess, which slowly forces its way to the surface, following the lines of least resistance.

3. The granulation tissue may caseate early, before the bony trabeculæ

are completely absorbed. The unabsorbed bone then perishes, forming a sequestrum. This *necrotic caries* is very common in the spine.

4. The granulation tissue not uncommonly undergoes *calcification*. This is said to be one mode of cure, especially when the area affected by the tuberculous disease is very limited, the small calcified nodule lying harmlessly embedded in the surrounding bone. Small necrosed fragments of cancellous bone with its spaces filled with calcified inflammatory products, are sometimes met with in the discharge from abscesses connected with angular curvature of the spine.

5. Lastly, if all sources of irritation are removed, the rarefying osteitis may cease to extend, and the granulation tissue become developed into bone, thus effecting a cure of the disease.

The destructive process extends not only into the bone, but also, usually at an early period, into the intervertebral fibro-cartilages. As the disease commences most commonly between the epiphyseal cartilage and the bone, the thin layer of cartilage is soon destroyed by the same processes as are observed in the destruction of articular cartilage in chronic inflammations of joints (p. 334). The granulation tissue then penetrates into the intervertebral disc, which is destroyed, after which the morbid process extends into the body of the next vertebra.

In whatever way the disease commences the most common cause of its persistence is the mechanical irritation of the diseased surfaces by the friction of movement, aggravated by the weight of the parts of the body above the affected vertebrae. In other cases the presence of sequestra, which cannot find a way out, may keep up the disease indefinitely. It seems probable that caries originally tuberculous may become simple in character as the disease progresses. The original tuberculous centre may completely caseate and soften, exciting inflammation in the tissue around it, and be thus eliminated, the subsequent progress of the disease being due to the mechanical causes above mentioned. In other cases the tuberculous process may infect the surrounding parts and maintain its characteristics to the end.

I know of no exact description of any *primary pathological changes taking place in the intervertebral discs*. As before stated, we are not in a position to deny that disease may originate in these structures, for by the time the case comes to be examined after death the fibro-cartilage has often disappeared, and we find only the signs of rarefying osteitis in the vertebrae on each side. Luschka states that there is a synovial cavity in each disc, and that the lobes of the pulp correspond to the villi of a synovial membrane. If this be true it would be in this structure that any primary inflammation or deposit of tubercle would take place, and not in the dense fibrous and fibro-cartilaginous layers forming the outer zones of the disc.

The nature of the pathological changes being borne in mind, the coarser morbid appearances are easily understood.

Dry caries, or caries without suppuration, forms the simplest variety of the disease. It affects usually a limited portion of the spine, often only two vertebrae with the intervening intervertebral disc. The destruction of the bodies of the vertebrae in these cases often takes place somewhat rapidly, and at the same time the osseous tissue is softened by extension of the rarefying osteitis for some distance from the centre of the disease. In consequence of this the weight of the body above the diseased vertebrae causes a bending

forwards of that portion of the column, and a corresponding projection backwards of the spinous processes. A vertical section made through a spine thus affected shows the anterior common ligament thickened and swollen. The bodies of the affected vertebræ are softened and partly destroyed, the destruction being almost invariably more extensive anteriorly, as this part is exposed to the greater pressure when the spine is bent forwards. The intervertebral cartilage between the two vertebræ has more or less completely disappeared; if any remains it will be at the posterior part. The opposed surfaces of the vertebræ are covered by granulation tissue, and are sometimes mutually adapted to each other as the result of friction. In the cancellous spaces of the bone on each side the normal medulla has disappeared, and its place is taken by the same tissue. The periosteum covering the remaining portion of the vertebræ and frequently also that of the vertebræ above and below is affected by osteo-

Fig. 602. — Angular Curvature of the Dorsal Spine from Caries and Ankylosis.

Fig. 603. — Caries of Bodies of Lumbar Vertebrae: no attempt at Ankylosis.

plastic inflammation, irregular spiculated nodules of new bone being formed beneath it. The spines, the transverse and the articular processes being unaffected, there is no dislocation, and consequently the spinal canal is but little if at all narrowed. Should the disease cease at this stage, as it frequently does, the granulation tissue of the opposed surfaces coalesces, and subsequently becomes developed into bone, and the angle formed by the bending of the spine is filled up by a buttress of bone formed beneath the periosteum, and thus the spine, although retaining its deformed position, may become as strong as before the disease (Fig. 602).

In other cases of caries of the spine the disease is more extensive, commencing from many centres, often situated in different vertebræ and unconnected with each other. These centres are situated most commonly in the immediate neighbourhood of an intervertebral disc, but are not uncommon on the surface of the body beneath the periosteum, and are sometimes deeply

placed in its substance. A macerated specimen shows the bone to be eaten out into irregular hollows, around which the cancellous tissue is more porous than natural. In a fresh specimen these hollows are filled with caseous granulation tissue. When the disease commences near an intervertebral disc, this is soon destroyed, and the contiguous surface of the next vertebra becomes implicated (Fig. 603). The friction of the diseased surfaces against each other then aggravates the process, and leads to more rapid destruction at the parts where they are in contact.

In some cases instead of the bone being more spongy than natural round the excavations, it may be seen in the macerated specimen that the osteitis has assumed an osteoplastic form, the cancellous tissue being denser than natural, and its trabeculae thickened, just as a zone of dense bone is often found around a chronic abscess in the cancellous ends of the long bones.

When the disease leads to suppuration, the pus frequently raises the anterior common ligament from the vertebræ for some distance. This is more likely to happen when the resulting chronic abscess has opened externally and become septic. Rapid destruction of the intervertebral discs with which the pus comes in contact then frequently takes place. It is not uncommon to find the vertebræ for some distance above and below the centre of disease bare in front, and looking as if macerated, while the cartilages between them have more or less completely disappeared.

The chronic abscesses forming in connexion with caries of the spine are directed to the lateral aspect of the bodies of the vertebræ by the great thickness of the anterior common ligament. As the pus accumulates the abscess makes its way, as in the case of chronic abscesses generally, in the direction of least resistance, usually following the course of a vessel, or burrowing beneath the fasciæ covering muscles. Thus in disease of the dorsal vertebræ, the abscess follows the intercostal artery and passes between the ribs with the posterior branch, appearing under the skin of the back as a "dorsal abscess." In the lumbar region the abscess may in the same way follow a lumbar artery and form a "lumbar abscess," or enter the sheath of the psoas muscle and form a "psoas abscess," pointing below Poupart's ligament.

When the caries is complicated by necrosis, the sequestra are frequently so entangled in the excavated cavity in the body of the vertebræ, covered in in front by the thickened anterior ligament, that it is impossible for them to make their way to the surface, and thus even if the disease ceases to extend, suppuration may be indefinitely prolonged till it causes the death of the patient.

The angular projection backwards of the diseased part of the spine, corresponding in extent to the amount of destruction of the vertebræ, forms usually the most marked feature of the disease (Figs. 604—606). The mechanism of this is easily understood by reference to the pathology of the affection. The bodies (one or more) of the vertebræ, being softened or partly destroyed, at last give way under the weight of the upper part of the body; the upper part bends forwards, and the spine projects posteriorly. At the same time that the upper part bends forwards, the lower part of the spine rarely maintains the upright position as it did in Fig. 602. In the great majority of cases there is a compensating incurvation just below the excurved vertebræ, and in this way the upper part of the body is carried erect. The angle of excurvation varies according to the number of vertebral bodies destroyed, and the extent

of the loss of substance and the part of the spine affected. In the cervical and lumbar regions the natural curve having its convexity forwards is at first straightened out, angular projection of the spines occurring only in very extreme cases. The greater the number of vertebræ affected the more obtuse will the angle be. When one vertebra is alone or chiefly diseased, three spinous processes will project to form the angle, that of the diseased vertebra being the apex. If two or three be diseased, five spinous processes usually enter into the formation of the angle of excursion, and then the whole of this portion of the column will be displaced backwards, giving a thickened and broadened base to the excursion in the lateral direction. In the dorsal region, if a single vertebra is diseased, the projection is usually very marked and sharp as the bending forward of the vertebra turns the long oblique spine almost directly backwards, forming a sharp prominence. In the lumbar

Fig. 604. — Natural Curve of Spine.

Fig. 605. — First early Change of Curve in Angular Curvature.

Fig. 606. — Change of Curve of Spine in Advanced Stage of Angular Curvature.

region, where the spines are short and point directly backwards, the projection is more rounded.

That the weight of the upper part of the body is not the sole element concerned in the production of the angular deformity is sufficiently proved by the fact that it is not altogether prevented by keeping the patient throughout in the recumbent position. Under these circumstances, curvature is still produced by the tonic contraction of the various muscles which pass longitudinally from one part of the spine to another. The part played by the muscles in this respect has been insisted upon by Lannelongue and Cheyne, and, as we shall see, has an important bearing upon the mode of treatment adopted in the early stages of spinal disease.

It very rarely happens that the cord is pressed upon by the displaced bones, though it may be affected secondarily by disease of the membranes, or by the pressure of inflammatory products outside them (see *Slow Compression of the Cord*, p. 485).

The **most common seat** of caries of the spine is the lower dorsal or the junction of the dorsal and lumbar regions. It is not uncommon in the middle

dorsal, and may occur at any part. R. W. Parker states that in 149 cases, the disease was in the cervical region in 9, in the dorsal in 82, in the dorso-lumbar in 21, and in the lumbar or lumbo-sacral in 37.

**SYMPTOMS.**—Caries of the spine commonly begins, especially in children, in a very insidious manner. It occurs usually in strumous children, and is generally referred to a fall or blow on the back. The symptom that most often first attracts attention is the child's attitude, which is altered and very characteristic. The body is held stiffly straight and upright: it is neither bent nor turned to one side when the child moves, but the spine is moved as a whole and in a rigidly fixed manner. The shoulders are raised, the chin is thrown up, and the toes are slightly turned in. The child walks with great caution, and very stiffly.

One of the earliest symptoms complained of is often an ill-defined superficial pain extending round the trunk, more severe, perhaps, on one side than on the other, and occasionally referred to the stomach. After a time the child becomes unable to stand upright unsupported, has a tendency to lean the body forwards, or to support it by resting the hands on the knees, or by seizing hold of anything that will serve as a temporary support, such as a chair or table. If asked to pick up an object from the floor, it will go carefully down upon its hands and knees instead of stooping in the natural way. It will be found also that the child experiences great difficulty in raising itself without assistance from the horizontal into the sitting position, or in turning sideways in bed without the use of its arms. On examination, one or two of the spines, usually about the middle of the back, will be found to be a little more prominent than the rest; and on pressing or tapping upon them, pain may be complained of. The child becomes stunted in its growth; and, if the disease be not arrested by proper treatment, will continue more or less hump- or round-backed for life. In other cases the disease will run on to the formation of abscess, as will immediately be described, tuberculous disease occurring elsewhere, and death eventually resulting.

In *adults*, the danger and the symptoms vary according to the seat of the affection. It is most dangerous, often indeed rapidly fatal, when the cervical vertebrae are implicated; for, as the bodies of these are shallow, caries readily penetrates to the spinal canal, and the cord or its membranes may thus be implicated. When the dorsal or lumbar vertebrae become diseased, the affection is not so immediately serious to the life, as it may be to the figure, of the patient. In adults, it often commences with obscure flying pain in the loins or back, resembling rheumatism, shooting round the body or down the thighs. On examining the spine, which feels weak to the patient, and which, as in the child, is incapable of supporting him or of enabling him to raise or turn himself without assistance, tenderness on pressure or on tapping may be experienced at one point, and he will wince when a sponge wrung out of hot water is applied to this part of the spine; although there may be no appearance of excoriation, the skin covering it is often hyperaesthetic. After a time, however, the spinous process of one or more vertebrae will be found to project distinctly beyond the general line of the column. The part becomes the seat of constant aching pain, increased by movement or by pressing upon the head or shoulders. It must, however, be remembered that caries of the bodies of the vertebrae may take place to a considerable extent with little or no angular curvature. In these cases all the ordinary symptoms of caries of the spine

will be found, except the excurvation. It will be observed that the spine has lost its natural free mobility and flexibility, moving fixedly, stiffly, and as a whole, when the patient leans forwards or sideways. If asked to stoop down the patient will incline the body forwards rigidly without bending the spine. He cannot put on or lace up his boots. When laid flat on his back, he cannot raise himself into a sitting position without the aid of his hands or elbows, and he cannot turn sharply or suddenly over upon his face, but struggles with outstretched arms in vain attempts to do so. Occasionally the incipient curvature, when it occurs, assumes more of a lateral than of an angular direction; and in one fatal case I have seen the spine actually bent backwards, so as to be incurvated at the seat of the disease. In some cases, the true angular excurvation dependent on caries of the bodies of the vertebræ may be associated with the ordinary lateral curve of debility. The lower limbs become weak, and the patient walks with a peculiar shuffling tottering gait, the legs being outspread, and the feet turned out. The weakness of the limbs is especially marked in going upstairs, and may be tested by directing the patient to stand unsupported on one leg, and raise the other so as to place the foot upon the seat of a chair, which he will probably be unable to do. The deformity of the spine may slowly increase; the patient may become unable to stand; and paralysis of the muscles of the lower extremity may come on.

Pleuritic attacks of a localized character dependent on extension of the inflammation to the contiguous pleuræ have been observed in rare cases of caries affecting the dorsal spine.

**Abscess** commonly makes its appearance as the disease progresses; and in some cases it occurs before any of the other signs except pain and weakness of the spine, and certainly before any deformity. When the abscess appears, as Stanley observed, the pain consequent on irritation of the spinal nerves is often lessened for a time.

It must not be supposed that abscess necessarily follows in all cases. In children especially we often meet with great excurvation without any suppuration. In adults it is very rare to see angular curvature without the formation of an abscess. The exact causes that determine the formation of pus are not certain in all cases. In many it is undoubtedly due to the irritation caused by the friction of the diseased surfaces against each other, and proper treatment adopted early will do much to prevent it. Suppuration is also more likely to occur when the patient is poorly fed and exposed to general unhygienic surroundings.

In cases which recover without suppuration the diseased bodies become fused together into a single mass, across which bridges of osseous tissue are thrown out, so as to strengthen the otherwise weakened spine. This is the natural mode of cure of angular curvature of the spine, and the only way in which it can take place when once the disease has advanced to any considerable extent.

When pus forms in connexion with caries of the spine, the situation and course of the abscess depend mainly upon the part of the spine affected: thus, for instance, when the cervical vertebræ are diseased, the abscess will come

Fig. 807. — Attitude of Child in Angular Curvature in Advanced Stage.

forwards behind the pharynx, and may occasionally extend under the mastoid muscle to the side of the neck, where it opens ; sometimes, but very rarely, it passes into the chest, and in other cases into the axilla.

When the disease is seated in the upper or middle dorsal spine, the pus most commonly passes backwards between the posterior ends of the vertebræ forming a *dorsal abscess*. In some cases, however, in which the middle vertebræ are diseased the abscess may extend downwards. When it takes this direction it most commonly passes under the ligamentum arcuatum intervertebrale and thus enters the sheath of the psoas muscle and takes the course there described immediately. In rare cases it may pass between the pillars of the diaphragm with the aorta and follow the large vessels in the subperitoneal tissue superficial to the fascia of the psoas and iliacus, forming an abscess filling the iliac fossa and pointing above Poupart's ligament, or it may extend downwards into the pelvis and escape with the gluteal artery through the great sciatic notch, giving rise to a large abscess in the gluteal region. It is remarkable that in caries of the dorsal vertebræ the pus does not tend to encroach on the chest or the pleural cavity. When the lower dorsal or lumbar vertebræ are diseased the pus enters the sheath of the psoas muscle, thus constituting the common affection termed **Abscess**. A psoas abscess follows the course of the muscle from which it derives its name. It is firmly bound down in front by the fascia covering that muscle and the iliacus, which is usually considerably thickened ; it is never perforated by the pus. The psoas muscle is usually extensively destroyed. The pus is prevented from extending downwards into the pelvis by the attachment of the ilio-psoas fascia to the brim ; there is nothing to limit its extension outwards over the whole surface of the iliacus, though the attachment of the fascia to the crest of the ilium prevents its passing beyond that point. In some cases we find that a psoas abscess usually extends outwards, forming a fluctuating swelling filling the iliac fossa. As the accumulation increases it passes beneath Poupart's ligament most commonly by a somewhat narrow neck situated in the line of the anterior crural nerve. It is thus at first situated to the outer side of the femoral vessels. Fluctuation can readily be felt between the swelling on the thigh and that in the iliac fossa. The very distinct impulse communicated to the part outside the abdomen by coughing, and this, combined with the somewhat sudden appearance of swelling on the thigh, may make it in some respects resemble a hernia. When reaching the thigh the abscess extends downwards to the outer side of the femoral vessels for a short distance till it meets the profunda, and following this vessel it passes behind the femoral artery, which can be felt stretching over it in front. It then continues its course under the adductor longus, and forms a large cavity at the inner side of the thigh, having the profunda stretched over it internally, the adductor magnus behind it, and the adductor longus in front. Processes frequently extend from the main cavity along the branches of the profunda. The most common of these prolongations winds round the neck of the femur with the branches of the internal circumflex, and passing through the interval between the adductor magnus and the quadratus femoris, becoming superficial immediately behind the greater trochanter, between it and the tuberosity of the ischium. The abscess extends beyond the upper part of the thigh, but it may continue its course downwards, until it reaches the popliteal space, and may even pass

nce downwards between the deep and superficial muscles of the calf ring the main vessels. I have seen an abscess, which took its origin in one of the dorsal vertebræ, opened by the side of the tendo Achillis (Fig. 693, Vol. I.). A psoas abscess when fully developed usually consists of three parts: a narrow track in the upper part of the psoas muscle, a wide opening in the iliac fossa, a second narrow part extending under Poupart's ligament and the femoral vessels, and a large cavity on the inner side of the thigh. The difficulty of properly draining such a cavity by an opening in the thigh is only too evident. In some cases the abscess may follow both psoas muscles, and project in each groin at the same time.

In the dorsal region, the abscess may pass backwards instead of downwards, and point in the loin, forming a *lumbar abscess*. More rarely it may pass amongst the layers of the abdominal muscles and point in front. In the case of the lower lumbar vertebræ and upper part of the sacrum the pus gets beneath the fascia covering the pyriformis, and then following the sciatic nerve, may point in the buttock beneath the gluteus maximus, or it may descend downwards to the ischio-rectal fossa. In all spinal abscesses small vessels derived from the diseased vertebræ are not uncommonly found in the pus. In the patient from whom Fig. 607 was taken several fragments of bone thus came away from an abscess that was opened in the fore part of the thigh. Much curdy matter is usually present, making it impossible in many cases to empty the sac by aspiration. The true source of origin of these abscesses may usually be determined by an examination of the spine, and by observing an impulse on coughing communicated to their extreme points of projection. In psoas abscess the attitude of the patient is often characteristic. He leans a little forwards with the thigh of the affected side slightly flexed and adducted in order to relax the affected muscle. Forced extension is accompanied by pain and aching of the back. The attitude and pain may resemble that of disease of the hip-joint. General oedema of the limb occasionally arises from a psoas abscess after it has reached the inner side of the thigh. In rare cases after opening, if septic inflammation follows, the abscess cavity may ulcerate into the hip-joint, causing acute and rapidly progressive arthritis.

**Compression of the Cord in Spinal Disease.—Compression paraplegia.**—As before stated, pressure upon the spinal cord is very rarely a direct result of displacement of the vertebræ in caries of the spine. It may occur in cases in which there is no deformity, and again recovery commonly takes place while the angular curvature remains unchanged or is not increasing. The true pathology of this complication was first pointed out by Michaud, and his observations have been fully confirmed by Charcot and others. In rare cases the pressure may be due to the formation of a cystic abscess pushing back the posterior common ligament against the cord. In other cases an abscess may gradually reach the surface, and rapid relief of pressure follows, when it is opened externally. Far more commonly, however, the ligament itself is invaded by tuberculous granulation-tissue, and at last perforated, or the abscess projects backwards on one or both sides of the ligament. The external surface of the dura mater is then affected, and a fungating tumor-like mass of tuberculous granulation-tissue forms upon it by which the cord is compressed (Fig. 608). The condition was described by Charcot as a form of external caseous pachymeningitis. The inner surface of the dura

forwards behind the pharynx, and may occasionally extend under the sternomastoid muscle to the side of the neck, where it opens; sometimes, though very rarely, it passes into the chest, and in other cases into the axilla.

When the disease is seated in the upper or middle dorsal spine, the abscess most commonly passes backwards between the posterior ends of the ribs, forming a *dorsal abscess*. In some cases, however, in which the middle dorsal vertebræ are diseased the abscess may extend downwards. When it takes this direction it most commonly passes under the ligamentum arcuatum internum, and thus enters the sheath of the psoas muscle and takes the course to be described immediately. In rare cases it may pass between the pillars of the diaphragm with the aorta and follow the large vessels in the subperitoneal tissue superficial to the fascia of the psoas and iliacus, forming an accumulation filling the iliac fossa and pointing above Poupart's ligament, or it may extend downwards into the pelvis and escape with the gluteal artery through the great sciatic notch, giving rise to a large abscess in the gluteal region. It is remarkable that in caries of the dorsal vertebræ the pus does not tend to encroach on the chest or the pleural cavity. When the lower dorsal or upper lumbar vertebræ are diseased the pus enters the sheath of the psoas or the substance of the muscle, thus constituting the common affection termed **Psoas Abscess**. A psoas abscess follows the course of the muscle from which it derives its name. It is firmly bound down in front by the fascia covering that muscle and the iliacus, which is usually considerably thickened and is never perforated by the pus. The psoas muscle is usually extensively destroyed. The pus is prevented from extending downwards into the pelvis by the attachment of the ilio-psoas fascia to the brim; there is nothing to limit its extension outwards over the whole surface of the iliacus, though the attachment of the fascia to the crest of the ilium prevents its passing beyond that point. Thus we find that a psoas abscess usually extends outwards, forming a large fluctuating swelling filling the iliac fossa. As the accumulation increases it passes beneath Poupart's ligament most commonly by a somewhat narrow neck situated in the line of the anterior crural nerve. It is thus at this part situated to the outer side of the femoral vessels. Fluctuation can readily be felt between the swelling on the thigh and that in the iliac fossa. There is very distinct impulse communicated to the part outside the abdomen on coughing, and this, combined with the somewhat sudden appearance of the swelling on the thigh, may make it in some respects resemble a hernia. After reaching the thigh the abscess extends downwards to the outer side of the vessels for a short distance till it meets the profunda, and following that vessel it passes behind the femoral artery, which can be felt stretching across it in front. It then continues its course under the adductor longus, and forms a large cavity at the inner side of the thigh, having the gracilis stretched over it internally, the adductor magnus behind it, and the adductor longus in front. Processes frequently extend from the main cavity along the branches of the profunda. The most common of these prolongations is one winding round the neck of the femur with the branches of the internal circumflex, and passing through the interval between the adductor magnus and the quadratus femoris, becoming superficial immediately behind the great trochanter, between it and the tuberosity of the ischium. The abscess seldom extends beyond the upper part of the thigh, but it may continue its course downwards, until it reaches the popliteal space, and may even pass some

distance downwards between the deep and superficial muscles of the calf following the main vessels. I have seen an abscess, which took its origin in disease of the dorsal vertebræ, opened by the side of the tendo Achillis (Fig. 93, Vol. I.). A psoas abscess when fully developed usually consists of four parts: a narrow track in the upper part of the psoas muscle, a wide expansion in the iliac fossa, a second narrow part extending under Poupart's ligament and the femoral vessels, and a large cavity on the inner side of the thigh. The difficulty of properly draining such a cavity by an opening in the thigh only is evident. In some cases the abscess may follow both psoas muscles, and project in each groin at the same time.

As in the dorsal region, the abscess may pass backwards instead of downwards, and point in the loin, forming a *lumbar abscess*. More rarely it may burrow amongst the layers of the abdominal muscles and point in front. In disease of the lower lumbar vertebræ and upper part of the sacrum the pus may get beneath the fascia covering the pyriformis, and then following the nerves, may point in the buttock beneath the gluteus maximus, or it may extend downwards to the ischio-rectal fossa. In all spinal abscesses small sequestra derived from the diseased vertebræ are not uncommonly found in the pus. In the patient from whom Fig. 607 was taken several fragments of bone thus came away from an abscess that was opened in the fore part of the thigh. Much curdy matter is usually present, making it impossible in many cases to empty the sac by aspiration. The true source of origin of these abscesses may usually be determined by an examination of the spine, and by feeling an impulse on coughing communicated to their extreme points of presentation. In psoas abscess the attitude of the patient is often characteristic. He stands leaning a little forwards with the thigh of the affected side slightly flexed and adducted in order to relax the affected muscle. Forced extension is accompanied by pain and aching of the back. The attitude and pain may thus resemble that of disease of the hip-joint. General œdema of the limb may occasionally arise from a psoas abscess after it has reached the inner side of the thigh. In rare cases after opening, if septic inflammation follows, the abscess cavity may ulcerate into the hip-joint, causing acute and rapidly destructive arthritis.

**Slow Compression of the Cord in Spinal Disease.—Compression Paraplegia.**—As before stated, pressure upon the spinal cord is very rarely the direct result of displacement of the vertebræ in caries of the spine. In fact it may occur in cases in which there is no deformity, and again recovery very commonly takes place while the angular curvature remains unchanged or is even increasing. The true pathology of this complication was first pointed out by Michaud, and his observations have been fully confirmed by Charcot and others. In rare cases the pressure may be due to the formation of a chronic abscess pushing back the posterior common ligament against the cord. Such an abscess may gradually reach the surface, and rapid relief of pressure will follow, when it is opened externally. Far more commonly, however, the ligament itself is invaded by tuberculous granulation-tissue, and at last perforated, or the abscess projects backwards on one or both sides of the ligament. The external surface of the dura mater is then affected, and a fungating button-like mass of tuberculous granulation-tissue forms upon it by which the cord is compressed (Fig. 608). The condition was described by Charcot as a "kind of external caseous pachymeningitis." The inner surface of the dura

mater is not affected, and the subsequent changes in the cord are due to pressure only. The morbid process in the dura mater may extend backwards on each side, but rarely forms a complete ring. The exact nature of the changes produced in the cord is not certain. According to Charcot a chronic inflammatory process occurs in the compressed segment—chronic transverse myelitis. It seems doubtful, however, whether myelitis occurs in all cases, and it is thought by some observers that the pressure causes anæmia followed by degenerative changes, and by others that a congested and oedematous condition results from the pressure on the veins and lymphatics. In any case secondary degenerative changes soon occur in the sensory tracts above the affected segment and in the motor tracts below it.

The effects of the chronic thickening of the dura mater, are, of course, not limited to the cord. The nerves passing through the diseased membrane also

Fig. 698.—Caries of Seventh Cervical and First Dorsal Vertebrae. A small abscess is situated behind the Discophagus and the Spinal Canal is narrowed by the projection of caseous material into it.

suffer, and many of the most characteristic symptoms are due to this. The nerves may also be pressed upon in some cases in their foramina by the falling together of two contiguous vertebrae as their bodies are destroyed.

**Symptoms.**—The symptoms must be divided into those due to pressure upon the cord itself and those arising from pressure on the roots of the nerves.

The earliest symptom of pressure on the cord is motor weakness in the muscles connected with the compressed segment and with the cord below it. As a rule there are no sensory phenomena at first, but occasionally pricking, formication or a sensation of constriction round the body may be present. As the pressure augments, the motor weakness may increase to complete paralysis. Complete or even partial loss of sensation is not common, as the sensory impulses are conveyed through the more central parts of the cord, which are less likely to be affected by the pachymeningitis. The knee jerks are usually exaggerated at an early stage, and in cases which recover this condition may persist ;

ankle clonus is also readily obtained, and in many cases there is rigidity of the limbs in the extended position. Sometimes if the extended limb be slightly bent, it will suddenly flex completely, apparently as soon as that point of flexion is reached which gives the flexors an advantage over the extensors. This condition has been termed "clasp-knife rigidity." In the later stages the limbs may become permanently flexed. There is no marked wasting of the paralysed muscles, nor are the electrical reactions of degeneration present. If the pressure affects the lumbar region the bladder may be paralysed, and retention, followed by dribbling, may result; but if it be above that point the bladder commonly empties itself periodically without the patient being able to influence the act by his will. The sensation of distension may, however, warn the patient in time to prevent his wetting his bed. In a case lately in University College Hospital the bladder acted purely automatically, but with such regularity that the child could be kept dry by being placed upon a bed-pan at fixed times. The rectum is much more rarely affected. In the great majority of cases of slow compression of the cord the symptoms are bilateral, but in very rare cases one lateral half of the cord only is affected.

The symptoms due to pressure on the nerve-roots are common, and often precede those due to compression of the cord. Pressure on the posterior roots causes at first uneasy sensations referred to the terminal branches of the affected nerve. Thus in cervical disease the referred pains may be experienced in the scalp, neck, or shoulders, or they may extend down the upper limbs. Dorsal caries may occasion pain along the distribution of the intercostal nerves when the upper part of the region is affected, or at the pit of the stomach or umbilical region when the disease involves the lower dorsal nerve roots. Pressure on the lumbar and sacral nerves is evidenced by pain referred along the course of the ilio-inguinal, external cutaneous, sciatic or other branches. The part supplied by the nerve may be hyperæsthetic. When the pressure becomes sufficient to block the root the part supplied by it becomes anæsthetic, but at the same time there may be intense neuralgic pain still referred to the terminal branches connected with the compressed root. This condition of "*anesthesia dolorosa*" as it has been termed is characteristic of compression of the posterior root.

Pressure on the anterior roots causes weakness followed by complete paralysis of the muscles connected with them. The distribution of the paralysis may in some instances be sufficiently definite to indicate exactly which roots are chiefly affected (see Vol. I., pp. 791, 792). The paralysis may be preceded by spasm or twitching. When the pressure is sufficient completely to block the root and thus to cut off the muscles connected with it from all connexion with the cord, rapid wasting ensues and the electrical reactions of degeneration will be observed.

The course of cases of this nature varies greatly, but on the whole the prognosis is favourable, and even after long periods of complete paraplegia gradual recovery often ensues. In cases in which there is incontinence of urine the patient is exposed to the risks of cystitis and its complications. Of 218 cases of paraplegia due to caries of the spine collected by Myers, 55 per cent. were known to have recovered and 3.5 per cent. died; the results in the remaining cases were not known.

**Acute Spinal Meningitis** is a very rare and fatal complication of caries

of the spine, but it is occasionally met with in those cases in which the destruction of the bodies of the vertebrae has exposed the dura mater so that it comes to form part of the wall of a chronic abscess. Even then it rarely if ever occurs, except as the result of decomposition of the discharges after the abscess has been opened, as a consequence of which the membrane may slough.

DIAGNOSIS.—The diagnosis of caries of the spine is made at the first sight of a patient affected by the disease, when once the angular deformity has taken place. It is, however, difficult before excurvation occurs, being indicated at this period only by the existence of pain in the back, and by some symptoms of spinal irritation. At this stage it may be mistaken for spinal or intercostal *neuralgia*, for *rheumatism*, or for *stone in the kidney*. The persistence, however, of a continuous fixed pain in the back should always lead to a suspicion as to the true nature of the disease, lest the grievous error be committed of treating as mere neuralgia or rheumatism what may turn out to be disease of the spine itself. Here the tenderness on pressure, the increased sensibility to the application of heat will determine the seat of the affection. The pain elicited by rotation or by antero-posterior movement is a very valuable symptom. In some cases pain on bending backwards is most complained of. The patient can stoop forwards, but if bent backwards suffers much. So also pressure on the head or shoulders greatly increases the pain of the part affected. The shape of the back, with loss of the natural curves of the spine with a tendency, though it be very slight, to projection of some of the spinous processes, the feeling of weakness in the back, the difficulty in rising from a sitting or horizontal position, in turning, or in standing on one leg unaided, the loss of the natural flexibility of the spine, and especially the occurrence of these symptoms in early childhood or youth, at a period when the other diseases with which it may be confounded rarely occur, and are still more rarely persistent, should lead one to suspect the existence of caries of the spine.

The diagnosis between *abscesses* localized in the situations mentioned, and those arising from diseased spine, is not always easy; as purulent collections of various kinds may form in the areolar tissue in the neighbourhood of the vertebral column, without any disease existing in it. Thus, a large *psoas* abscess descending in the sheath of the muscle and presenting under Poupart's ligament, may occur without any disease of the vertebrae. In these cases of simple abscess, the diagnosis from the *psoas* abscess dependent upon vertebral disease may be practically impossible, for in some cases the presence of the abscess may be the only symptom of spinal disease. As *psoas* abscess dependent upon vertebral caries almost invariably presents in the groin, and a large abscess in the groin may arise from various other conditions, independently of such vertebral disease, the Surgeon must attend carefully to the diagnosis of these various conditions. *Abscess and fluctuating swellings in the groin* may arise from the following causes:—1, from large chronic collections of pus in the subcutaneous or intermuscular planes of areolar tissue; 2, from disease of the kidney with suppuration in the areolar tissue around it—*perinephritic abscess*; 3, from *pericaecal abscess* (on the right side only); 4, from *iliac abscess*, whether forming merely under the iliac fascia, or dependent on disease of the pelvic bones; 5, from *hip-joint disease*, the abscess being pelvic; 6, from large *buboes* or glandular abscesses; 7, from an *empyema* perforating the pleura and finding its way down behind the diaphragm; 8, from *serous* or *hydatid* cysts; and 9,

from femoral hernia with fluid in the sac. These various collections may, however, with a little caution be readily distinguished from the ordinary form of spinal abscess that descends along the psoas muscle. In the first place, in all these cases there is an absence of that dorsal pain and tenderness, with more or less excurvation, which, though not invariably present, is commonly met with in psoas abscess. Then, again, if the collection be *perinephritic*, there will have been previous, or there are co-existing symptoms of renal disease. I have, however, seen an abscess dependent on caries of the vertebræ not only assume the perinephritic form, but open into the pelvis of the kidney, thus simulating chronic pyelitis. In this case the diagnosis was made by a careful examination of the pus, in which molecular masses of carious bone were found. The chemical and microscopic examination of the pus in all cases of doubt should never be omitted. If there be caries, it may present unmistakable evidence of the presence of disintegrated bone. If it occur in the *areolar tissue around the cæcum*, the pus will be peculiarly offensive, will present itself in a less distinct manner, and will probably be associated with symptoms of intestinal irritation. Moreover, perinephritic or pericæcal abscesses being superficial to the iliac fascia, do not extend below Poupart's ligament except in some rare cases, in which the abscess is acute and forces its way irrespectively of the attachments of the fasciæ. Thus I have seen the pus in a pericæcal abscess pass under Poupart's ligament, and present as a large sloughy abscess at the upper and outer part of the thigh. In those rare cases in which an *empyema* has found its way between the layers of the abdominal muscles, and presented in the groin, the examination of the chest will point out the nature of the affection. In *abscess connected with disease of the hip-joint*, there will be special local evidences of the source of the pus. The only real difficulty consists in diagnosing a psoas abscess dependent on disease of the vertebral column, before it reaches the thigh, from *iliac abscess*, whether it take its origin in the loose areolar tissue of the iliac fossa, or be connected with disease of the corresponding bone; and in the latter cases the difficulty is often not a little increased in consequence of the iliac abscess finding its way into the sheath of the psoas muscle. If the iliac abscess be superficial to the fascia iliaca, it very rarely passes beneath Poupart's ligament, owing to the firm attachment of these two structures to each other. In very rare cases such abscesses find their way along the spermatic cord or down the femoral sheath, and thus leave the abdomen, but these could not be confounded with psoas abscesses. When the collection of pus forms beneath the fascia iliaca, there is nothing to prevent its extending to the psoas or passing down under Poupart's ligament, and the determination of its origin whether from disease of the ilium, or vertebræ, or from a strain, can be made only by the presence or absence of the symptoms of disease of the spine. Whenever the abscess is beneath the fascia, there are some signs of irritation of the ilio-psoas muscle, which are usually wanting when the pus is in the subperitoneal tissue. These signs are most marked when the abscess extends along the whole length of the psoas. There is then an inability to stand upright, to extend the leg, and pain is complained of in walking. Psoas abscess also, in many cases, appears on the thigh suddenly, the patient finding, on washing himself in the morning, that he has a large soft tumour in the groin; whereas iliac abscess comes on more gradually, and presents in a more diffused and less circumscribed manner.

Iliac and psoas abscesses require to be diagnosed also from certain forms of *aneurism of the abdominal aorta or iliac arteries*; which, having become diffused by rupture of their sac, have formed large non-pulsating extravasations in the sheath of the psoas and in the iliac fossa. In such cases the previous history, the absence of distinct fluctuation, and possibly stethoscopic examination, together with the rapid increase of the tumour, will indicate the true nature of the case.

In other cases, again, when the abscess, after deeply burrowing, has perforated the fascia lata, its feel closely resembles that of certain *fatty tumours*. Here the possibility of diminishing the size of the swelling on pressure, the impulse on coughing, and the absence of a solid edge to the swelling, enable the Surgeon to make the diagnosis.

From *femoral hernia* the soft and fluctuating character of the swelling, its gradual return when pressure is taken off, its situation external to or below the femoral vessels, and the total absence of gurgling, constitute the chief distinguishing characters.

*Large serous collections and hydatid tumours* are occasionally met with in the iliac fossa and groin, presenting all the characters of chronic abscess; from which, however, the character of the fluid removed by aspiration will immediately distinguish them.

**PROGNOSIS.**—The prognosis is necessarily unfavourable. It has two aspects: 1. As to the persistence of Deformity; 2. As to the Life of the patient.

1. **Deformity.**—The angular curvature arising from caries of the bodies of the vertebræ is necessarily an incurable deformity. The diseased spine is soldered and held together by fusion of the partly destroyed vertebral bodies; and any attempt at straightening this excurvation would be attended with the greatest risk, from danger of exciting irritation of the spinal meninges, or opening the spinal canal. When excurvation has taken place, there has been loss of substance; and this cannot be repaired. Hence the spine must remain shortened in front and bent out posteriorly, giving rise to the ordinary forms of hump-back.

2. **Life.**—So far as life is concerned, the prognosis will depend on several conditions. The first is whether the disease is accompanied or not by suppuration. When suppuration occurs, much will depend on the extent of the caries: if several vertebræ be affected, so that the curve is very long, the disease is necessarily highly dangerous from the extent of osseous structure implicated. It was long ago remarked by Boyer that the most fatal cases were generally those in which the spine preserved its straight position; whereas, when it was much curved, death seldom resulted. The truth of this remark I have had frequent occasion to verify; and the circumstance would appear to be owing to the fact that, when the spine continues straight at the same time that the bodies of the vertebræ are tuberculous and carious, ankylosis cannot occur, so that the spinal canal is open and the cord irritated; whereas, when they have fallen together and very considerable angular deformity has resulted, ankylosis more readily takes place, and thus an imperfect cure is effected. The size of the abscesses, and the amount of discharge from them, must also necessarily seriously influence the result. If they be very large, and continuously discharging, hectic and consequent death will probably supervene. The presence of sequestra which will not come away, and prevent healing, adds greatly to the gravity of the case.

The gravity of the prognosis is increased when symptoms of slow compression of the cord set in, but not to the extent that might have been supposed. A very large proportion of the cases recover even after complete paralysis or die from causes unconnected with the pressure of the cord.

Caries of the spine is more fatal in adults than in children. In those rare cases in which it commences after middle life it is almost invariably fatal.

**TREATMENT.**—The first principle in the treatment of caries of the spine is to take off the weight of the part of the body above the diseased vertebræ, and at the same time to fix the vertebral column so as to prevent the friction of the diseased surfaces against each other and to encourage recovery by ankylosis. This object may be attained by two methods: 1, the maintenance of rest in the horizontal position, and, 2, the application of some mechanical apparatus. These methods cannot be employed indiscriminately; one will be more suitable than another at different ages, in different stages of the disease, or according as it affects different portions of the column. Whatever method of securing rest be chosen no time must be lost in adopting it as soon as the existence of the disease is recognised.

**Treatment by the recumbent position** is very efficacious and except in young children should be the general plan adopted in the earlier stages of the disease. When practicable the patient may be laid on a properly constructed prone couch. The prone position is certainly preferable to the supine; for not only is the projecting angle formed by the excurvated spine not injuriously compressed, as it would be in the supine or lateral position, but the patient is more comfortable. At the same time, the back not being the lowest part of the body, there is less tendency to congestion of the diseased parts.

Opinion differs amongst Surgeons as to the value of *extension* in the treatment of spinal caries. To employ this treatment with any idea that the curvature can be diminished by separation of the diseased vertebræ is obviously erroneous and harmful, but gentle extension is undoubtedly serviceable as a means of diminishing the irritation which results from the pressure of the diseased bones together by the tonic contraction of the muscles (p. 351). Extension thus employed is a valuable adjunct to complete rest in the recumbent position, especially in early acute cases and when any symptoms of compression of the spinal cord are present. In applying extension the head is secured to the upper part of the bed by soft straps passing beneath the chin and occiput, and a weight is attached to the lower limbs by means of strapping as in the treatment of hip-joint disease. Formerly the patient was kept in the recumbent position for many months, seldom less than twelve or eighteen, till all the acute symptoms had disappeared. Since the introduction of the treatment by the plaster jacket immediately to be described, this is no longer necessary. If the symptoms are very acute, the prone couch may be used for a short time, but as soon as possible the plaster jacket should be applied and the patient allowed to move about.

**Treatment by Mechanical Support.**—The most efficient of all means of treating caries of the lower dorsal and lumbar regions of the spine is the application of the plaster of Paris jacket as recommended by Sayre of New York. The following is a brief summary of the details of this method.

The patient being stripped to the waist, a thin closely woven vest without sleeves is drawn over the body. It must be stretched so as to lie perfectly smooth, and may be kept from wrinkling by a piece of bandage passing

between the legs and pinned to its lower edge in front and behind. The patient is then placed under a tripod stand, to the apex of which is attached a block-and-fall arrangement carrying a horizontal iron bar; a padded collar is buckled round the head and chin, while padded stirrups are passed under the arms; straps are then passed separately from the collar and arm-stirrups to the iron bar above (Fig. 609). By shortening or lengthening these straps, the relative tension upon the head and arms can be adjusted with

Fig. 609.—Application of Sayre's Plaster Jacket

Fig. 610.—Sayre's Jacket Applied.

nicety. The indication that the proper amount of extension has been made with the pulleys is the comfort experienced by the patient. He must on no account be raised completely from the ground. When thus suspended, the spine becomes straighter, the ears are lifted from the shoulders, and the diseased surfaces of the vertebrae are prevented from pressing upon one another.

A thick towel folded should be placed under the vest, over the fore part of the abdomen. When the case is dry, this is drawn out, and thus space

is left for expansion of the abdomen during meals. This precaution is a very important detail. Its omission may be attended with very inconvenient consequences.

Plaster of Paris bandages are then carefully applied round the body from immediately above the trochanters to the axillæ. Strips of thin perforated tin are next placed by the sides of the spine, and a second layer of plaster bandages passed round the whole (Fig. 610). The straps being now removed the patient is laid upon a mattress, great care being taken to keep the back extended while he is being moved lest the soft case be broken. As soon as he is upon his back the case must be carefully moulded to the crests of the ilia by firm pressure with the hands. If there is much projection of the spines a pad of soft lint or cotton wool must be placed on each side of the prominence to prevent injurious pressure. Sayre strongly insists on the importance of attention to details. The bandages must be of "crinoline muslin," which will hold sufficient plaster in its meshes; the finest "Artist's plaster" must be used; the woollen jersey must be elastic, and fit accurately, and the case must be well moulded to the body by rubbing with the hands. When the case is dry a semilunar piece may be cut out under each arm and over each trochanter if necessary. The essential points to be attained by this treatment are: 1st, To extend the diseased spine to an extent sufficient to prevent friction of the carious surfaces against each other, not attempting, of course, to correct the angular deformity completely; 2nd, To maintain the spine in the extended position by a light and firm casing accurately moulded to the pelvis below so as to obtain a fixed point and closely embracing the thorax above, so that the weight of the head and shoulders may not be borne directly by the diseased bodies of the vertebræ. A well-made plaster jacket may be worn from two to six months without being changed.

Since the introduction of this treatment by Sayre various modifications have been suggested. In young children the tripod and pullies are unnecessary, as the jacket may be applied whilst the child is held by its mother or an assistant in an upright position with its arms over its head. In acute cases it is wiser to avoid the upright position altogether. This may be done by cutting a number of strips of plaster bandage one and a quarter times the circumference of the trunk. These may be wetted with equal parts of mucilage (B.P.) and water, which will delay the setting. A sufficient number of these are then arranged on a waterproof sheet overlapping each other, as in the ordinary many-tailed bandage. The patient, having the woollen jersey applied, is lifted and laid upon the bandages, which are folded over and rubbed smooth. There should be two layers of bandages, and the strips of perforated tin should be inserted between the first and second layers. This mode of application avoids any risk of dangerous extension of the diseased spine. After the application of a well-fitting plaster case there is usually great relief of pain, both in the spine and in the course of the nerves proceeding from the affected region. The respiration commonly becomes more easy. If the apparatus fits with sufficient accuracy the patient can bear the erect position and move about without pain.

It is evident that the jacket as above described cannot be of any use unless the disease is situated below the level of the folds of the axilla, as above this point the bandage cannot go. When the disease is above this point a special contrivance, termed by Sayre the "jury mast," is required to support the head

(Fig. 611). This consists of two bars of soft iron passing on each side of the spine and accurately moulded to it, and united between the shoulders by a cross bar, from the middle of which a vertical curved bar passes up behind the neck to above the middle of the head. At the end of this is a transverse arched bar of iron fixed on a pivot, so as to allow of rotation. To this the head is suspended by a padded collar passing beneath the jaw and occiput. The two upright bars are enclosed between the layers of the plaster jacket, and thus the weight of the head is transmitted directly to the pelvis. Jackets made of softened leather or "poroplastic" felt may be used instead of the plaster apparatus. They must be moulded to the patient, either while he is suspended or lying upon his back, with the arms well raised above the head. The "jury mast" can be fitted to these if required.

For very young children a double Thomas's hip-splint, from the upper transverse bar of which a well padded head-rest extends upwards, will be found a very efficient means of ensuring rest. The child can be carried by the nurse or moved in bed without the least disturbance of the spine.

Fig. 611.—Apparatus for Disease of Cervical or Upper Dorsal Spine. Plaster Jacket with "Jury Mast." (Sayre.)

Phelps of New York has introduced a wooden box-splint for the treatment of spinal disease in young children, which is highly spoken of by Watson Cheyne, and has the advantage that, if necessary, extension can be used with it. The splint consists of a wooden trough in which the patient lies, and which at its lower end is continued into two narrow troughs for the lower limbs. The box is about six inches deep, and must be broader than the patient, so as to allow room for padding. The sides are hollowed out for the arms, and opposite the buttocks the bottom of the box is cut away to allow defæcation. The patient lies on a mattress, pads are arranged between the patient and the sides of the box, and a broad bandage carried around all. The feet are

landaged to vertical pieces of wood attached to the ends of the leg-troughs, and if necessary elastic extension can be carried from the head to the upper end of the splint. When it is necessary to remove the splint, this should be done by lifting it off the child in the prone position.

Whatever apparatus may be used it is of the utmost importance that the patient should not be allowed to dispense with proper support for at least six months after all pain or other signs of active disease have disappeared, otherwise he is almost certain to suffer from a speedy relapse.

As before stated, the mode of treatment adopted must vary with the seat of the disease, the age and the circumstances of the patient. Treatment by the recumbent position alone is almost impossible amongst the children of the poor, as it requires constant attention from a nurse and a properly constructed couch which can be wheeled into the open air whenever possible. Even amongst the rich it is well to combine the recumbent position with the application of a leather or poroplastic splint. For the great majority of cases Sayre's plaster jacket is the most efficient apparatus. It requires no materials that are not always at hand, and can be applied by the Surgeon without the

assistance of an instrument maker. Its only disadvantages are that it cannot be taken off to wash the patient, and that it is apt to become foul and sores may form beneath it. In adults the plaster jacket, or one of leather or poroplastic should always be conjoined with the recumbent position. After all acute symptoms have subsided, the poroplastic or leather jacket will be found much superior to the old-fashioned steel supports.

**Counter-Irritation** by means of the actual cautery is occasionally useful in the treatment of spinal caries. The cases most likely to be benefited in this way are those in which the disease occurs in adults, and is accompanied by much pain in the early stages. The cautery should be drawn in a line on either side of the affected part of the spine. Nothing can be more unscientific or indicate a more profound ignorance of pathology than to employ counter-irritation after abscess has once formed.

The ordinary **constitutional treatment** that is adopted in strumous diseases must be employed in these cases. Much benefit will be derived from the use of cod-liver oil, iron, the phosphates, and above all good air—country or sea. As in all other cases where bone is diseased, at least three years must be devoted to the cure of a case of angular curvature. But that cure consists only in the preservation of life, not the removal of deformity, which is necessarily permanent.

**Treatment of Spinal Abscess.**—The formation of abscess should, if possible, be prevented by the employment of the means above described. Should suppuration unfortunately take place, the danger is greatly increased. A chronic abscess connected with caries of the spine should never be allowed to point or burst spontaneously. It must be opened or the pus evacuated in some way as soon as it has arrived at a point at which it can be clearly recognised and safely reached.

The various methods of treatment of chronic abscess have already been considered in Vol. I., p. 263 *et seq.*, so that it will be necessary now merely to indicate the chief considerations which determine the Surgeon in his choice.

Simple aspiration is now rarely employed, for although in a certain number of cases the pus does not reaccumulate, the method is too uncertain to be recommended. It may, however, be sometimes useful to aspirate a very large abscess once or twice before opening and draining it, so that the cavity may shrink and the early discharge be less profuse. Aspiration is a much more efficient method if, after the pus has been withdrawn, the abscess cavity is flushed out with water sterilized by boiling, and injected with iodoform emulsion (Vol. I., p. 264). A far more useful method of treatment, and one which should be followed in the large majority of cases, consists in opening the abscess, thoroughly flushing out and scraping its inner surface, so as to remove as much as possible of the caseous material which it contains, and then completely closing the wound. This plan is available for almost all cases, except those in which the abscess is on the point of bursting. A short incision is made into the abscess in such a position that all parts of its cavity can best be reached. Thus for psoas abscess the opening should be made close above Poupart's ligament external to the line of the vessels. Before the pus escapes the finger should be introduced so that the cavity may be explored while its walls are still tense. In dorsal or lumbar abscesses the finger may possibly be made to reach the diseased spine, and if a sequestrum be felt it might be removed. The pus is next evacuated, and then the cavity is flushed

with water sterilized by boiling and scraped with a Volkmann's spoon or Barker's flushing curette. In the case of a psoas abscess care must be taken in treating those parts of the cavity which lie close to the periosteum. Small sponges on long holders are also useful for the removal of the tuberculous material. Finally, after drying the cavity as thoroughly as possible, an ounce of 10 per cent. iodoform emulsion is introduced and the incision closed by sutures, including any muscular layers which have been divided. A wool dressing should be so arranged as to obliterate the cavity of the abscess as thoroughly as possible.

After this treatment, more or less serous exudation necessarily occurs into the remaining cavity, but in many cases it is quickly absorbed. If, however, the fluid increase, it should be withdrawn by an aspirator, and often it will not reaccumulate. In cases in which suppuration continues the same treatment may sometimes be repeated with success, but drainage will usually be required.

Drainage of these large abscesses should, as far as possible, be avoided, for it is attended with many risks and inconveniences. Although excellent results have been obtained by aseptic drainage, the treatment involves repeated dressings, and a long period of confinement to the recumbent position. The difficulty of ensuring asepsis is, however, great, for the patients are often children, the discharge profuse, and the opening in many cases necessarily in an inconvenient position. The patient is thus exposed to the risk of septic poisoning and hectic, with persistent and profuse suppuration kept up by putrefactive changes occurring in the pus.

In certain cases, however, drainage is unavoidable, and should be resorted to if the abscess is already on the point of bursting, or if other methods have been tried without success. The drainage must be free, and the opening should be made in a dependent position, and as far as possible from sources of contamination. In draining a psoas abscess the point usually selected is above the outer part of Poupart's ligament; an opening at the inner side of the thigh is rarely efficient, owing to the narrowness of the sac of the abscess where it passes beneath the femoral vessels, and is very unfavourably placed for maintaining asepsis. If the drainage from the anterior opening into a psoas abscess is imperfect a counter-opening behind is often most useful. This may be made at the outer edge of the erector spinæ, or, if the abscess occupies the iliac fossa just above the iliac crest opposite the interval between the external oblique and the latissimus dorsi.

In some cases of caries of the lower dorsal or lumbar vertebrae with psoas abscess, the incision may conveniently be made in the loin, as suggested by F. Treves, and then in addition to obtaining very direct drainage it may be possible to examine the diseased vertebrae with the finger. A vertical incision is made in the space between the last rib and the ilium immediately internal to the outer edge of the erector spinæ; this muscle is exposed and drawn towards the middle line, and the quadratus lumborum may then be cut through close to the transverse processes. The finger may now be thrust inwards along the anterior surface of a transverse process, so as to avoid the situation of the lumbar arteries. The tense sac of the abscess may then be felt. It is best opened by thrusting a pair of polypus forceps through its wall and expanding the blades. As soon as the pus flows, the finger may follow the forceps and feel for sequestra. This mode of opening has now been frequently adopted

with satisfactory results, and in suitable cases is certainly to be recommended. After a lumbar or psoas abscess has been opened for some time, and the discharge reduced to a very small amount, the patient may be allowed to move about with a proper plaster support, through which an opening may be made opposite the sinus for dressing the wound; or a poroplastic or leather support may be made which can be removed when necessary. Antiseptic dressing must be continued as long as any discharge persists.

The **Treatment of Paraplegia** in spinal caries must be based upon the important fact that the pressure is, in the large majority of cases, due to inflammatory products, and not to displacement of the bones. The treatment must therefore be directed to the removal of all causes which tend to increase the inflammatory processes in the neighbourhood of the bone disease. Of these causes the most important are the weight of the upper part of the body and tonic contraction of the muscles. These must therefore be counteracted by applying extension to the spine in the recumbent position. The application of weight extension has already been described at p. 491, but perhaps in cases of paraplegia elastic extension, as advocated by Horsley, is more efficient. This can readily be done by means of india-rubber "accumulators" attached to the extremities of the patient's body and to the upper and lower end of the bed respectively. The upper accumulators are fixed to the head by straps beneath the chin and occiput, and, unless the disease be cervical, to soft bands passing round the armpits; the lower ones are fixed to a pelvic band or to anklets. During this treatment the limbs should be rubbed to maintain their nutrition. By the employment of these means recovery slowly occurs in the majority of cases, but the process is a tedious one, and many months often elapse before any signs of returning power manifest themselves. The cure of cases of compression paraplegia, resisting other treatment, by operative interference may justly be considered one of the triumphs of modern surgery. In 1883 Macewen operated upon a boy who was the subject of complete paraplegia, with incontinence of urine and fæces, of two years' duration. He removed the laminæ of the 5th, 6th, and 7th dorsal vertebræ, and exposed a fibrous mass one-eighth of an inch in thickness, which was dissected off the outer surface of the dura mater. Improvement began twenty-four hours later, and after six months the patient could walk. Five years after the operation the boy was playing football at school. Of four other cases in which laminectomy was performed by Macewen two were successful; one died a week after the operation, and one after eight months from general tuberculosis. Macewen's cases were not published until 1888, but in the meanwhile other Surgeons had adopted the same treatment, and among those who have proved its utility in suitable cases are Horsley, Chipault, Thorburn, Arbuthnot Lane, Abbe and others. Chipault in 1890 was able to collect 35 cases in which laminectomy was performed for the relief of paraplegia complicating spinal caries; of these 20 were cured or markedly improved, and 10 died, but only three or four deaths could be attributed directly to the operation. In successful cases sensation, if impaired or lost, returns before motion, and the sphincters recover early. In unsuccessful cases either no improvement occurs, or a temporary improvement is followed by a relapse. The operation has proved more successful in children than in adults. Of 75 cases collected by Lloyd of New York, 20 were adults, 39 were children, and in the remainder the age was not noted. Of the 20 adults, 13 died at varying periods after the operation; of the 39 children 16 died.

In considering the indications for the operation of **laminectomy** it may be laid down as a general rule that it can rarely be justifiable until a fair trial has been given to the methods of treatment above described. If, however, in spite of thorough rest and the employment of extension in the early stages the symptoms are obviously increasing, or if in long-standing cases the treatment is not followed by improvement, the results hitherto obtained by operation certainly justify the Surgeon in having recourse to it. In a successful case of Thorburn's the operation was undertaken on account of the presence of secondary chest complications: in another, which ended fatally, for the relief of severe girdle pain which resisted all other treatment. Chipault insists upon the advantages of laminectomy in those rare instances in which the pressure is due to disease of the posterior arches of the vertebræ, for then the disease can be thoroughly removed and the pressure relieved by the one procedure. The operation is not justifiable if there are any signs of general tuberculosis or of active tuberculous disease in other parts of the body.

The operation must be conducted on the same lines as when performed for injury to the spine (Vol. I. p. 815). The incision should be so placed that its centre lies over the most prominent spinous process, and this, together with the spines and laminae of the vertebra above and below, should be removed. The condition of the tissues around the dura mater must now be carefully investigated. In some cases the pressure is due to dense inflammatory tissue which must be cautiously divided in the middle line and dissected from the theca. The latter should not be opened, and damage to the nerves must be carefully avoided. In many cases, however, the pressure is due to a small abscess projecting into the front of the canal (p. 485). This will appear as a small reddish or yellowish swelling, and should be opened from one side of the cord and scraped out with a sharp spoon. A drainage-tube is then inserted into the abscess cavity and the wound sutured and dressed antiseptically. The operation can be of little service in those rare cases in which the compression is caused by bony displacement, or is due to extension of the tuberculous disease to the membranes or even to the cord itself.

#### DISEASE OF THE CERVICAL SPINE.

Caries of the cervical spine presents several points requiring special consideration. It is much less frequent than in the dorsal and lumbar regions.

The most marked symptoms are pain and rigidity. The pain is increased by the slightest movement so that the child may instinctively endeavour to prevent this by steadying the head with the two hands. In attempting to look round the eyes only are moved or the whole body is rotated. The position of the head varies in different cases: thus it may be held stiffly erect or more often it is inclined laterally: less frequently there is marked flexion or even over-extension. Pressure on the vertex often causes great pain. Owing to the direction of the natural curve in this region and the shallowness of the bodies of the cervical vertebræ extensive disease may occur without any angular excorvation, the first effect of destruction of the bodies being to obliterate the normal curve.

**Disease of the Articulations between the Atlas and Axis, and between the Atlas and Occipital Bone** constitutes one of the most serious

forms of cervical caries. As the chief movements of the head take place in this position pain and rigidity are very early symptoms and the patient presents a characteristic and distressing appearance. The disease is especially apt to destroy one or both of the articulations between the atlas and axis, but the occipito-atlantal joints may be affected. In these cases gradual dislocation may occur, and sudden displacement with fatal compression of the cord is an accident to be carefully guarded against. Of 32 cases of dislocation collected by Lannelongue the atlanto-axial articulations were affected in 27, the occipito-atlantal in 3, and both in 2 cases. The most common form is the forward displacement of the atlas upon the axis, whilst when the occipito-atlantal joint is diseased one condyle may be dislocated forward. Displacement of the odontoid process backwards may result from destruction of the transverse ligament of the atlas, or from caries of the body of the axis.

Slow compression of the cord in the cervical region may result in complete paralysis of all the limbs, and death is likely to result from interference with the respiratory movements. Among the early symptoms of cervical caries are often the referred pains caused by irritation of the nerve roots; these may extend to the shoulder and down the upper limb or be situated in the side of the neck and along the distribution of the great occipital nerve.

Great care must be taken not to confound the disease in its early stages with simple muscular torticollis. In connexion with rheumatism a condition of painful rigidity of the cervical spine is sometimes met with in children which can be distinguished from commencing caries only by its course and the effect of treatment. Hysterical contractions of the lateral and posterior cervical muscles can usually be recognised by their association with other hysterical phenomena and by examination under an anæsthetic. Rheumatoid arthritis of the cervical spine occurs late in life, runs a chronic course and is not attended with the muscular rigidity of cervical caries.

Where suppuration occurs the abscess may come to the surface in the posterior part of the neck, but more often it forms on the front of the spine behind the pharynx.

**Retro-pharyngeal abscess** may form as a consequence of disease either of the bodies of the upper cervical vertebræ, or the articulations of the first two. It commences with induration and swelling of the areolar tissue at the back of the pharynx. Subsequently the swelling becomes softer and fluctuation perceptible. The posterior wall of the pharynx is pushed forwards against the posterior nares, giving a peculiar nasal tone to the voice, and if the abscess be large it may cause difficulty in breathing and swallowing. The formation of retro-pharyngeal abscess in young people should always lead to an examination of the cervical spine, although suppuration in this position may undoubtedly occur irrespectively of bone disease (see Chap. LVII.). The abscess may burst into the pharynx or, guided outwards by the prevertebral layer of the cervical fascia, it passes behind the carotid sheath to the side of the neck, where it usually appears at the posterior border of the sternomastoid. In rare cases the abscess burrows downwards, and reaches the superior mediastinum.

The **Treatment of Disease of the Cervical Spine** must be conducted on the same principles as that of angular curvature, by absolute rest and attention to the general health. The actual cautery may sometimes be of use in adults

before suppuration has taken place. When there is much pain it must be applied on each side of the spine at the back of the neck. As great and immediate danger may result from the sudden displacement of the vertebræ and consequent compression of the cervical cord, the head requires to be steadied by proper apparatus, calculated to support and steady its movements. Sayre's jacket with the "jury mast" (Fig. 611) is the most efficient apparatus for disease below the first two vertebræ. A leather splint embracing the shoulders and the upper part of the chest and back fitted with a broad collar for the neck and a support for the chin and occiput will be found to suit many cases. In disease of the atlas and axis, the head must be fixed absolutely so that no movement is possible. The patient should be confined to bed in the recumbent position, with a heavy sand-bag on each side of the head and a small pillow beneath the neck. Gentle weight extension by means of a collar holding on the chin and occiput attached to a cord passing through a pulley at the head of the bed is often useful in relieving pain. When the acute symptoms subside, an apparatus, such as is represented in Fig. 315, Vol. I., may be applied.

Retro-pharyngeal abscess is a serious complication, for when it bursts into the pharynx it empties itself imperfectly, and decomposition of the discharges ensues, thus perpetuating the disease. To avoid this, J. Chiene of Edinburgh recommends that it should be opened early, when possible, by an incision made behind the sterno-mastoid. The carotid vessels and pneumogastric nerve must be pushed forwards without injuring the sheath of fascia in which they are enclosed. The abscess can thus be treated antiseptically. In this way Chiene successfully treated a large abscess containing eight ounces of pus.

#### OTHER DISEASES OF THE SPINE.

**Gummata of the Spine.**—Cases of partial destruction of the bodies of the vertebræ by the formation of syphilitic gummata commencing beneath the periosteum have been recorded. The disease closely resembles ordinary caries of the spine in its symptoms, and the diagnosis can be made only by the history, and the co-existence of other syphilitic affections. The treatment is mechanical support in addition to the ordinary internal remedies.

**Rheumatoid Arthritis** may affect the spine. The intervertebral discs atrophy and bony outgrowths form from the bodies which may bridge over the spaces between them. The natural movements are thus restricted. Beyond this it causes no very definite symptoms, and it requires no special treatment.

**Tumours of the Spine.**—The bodies of the vertebræ are not uncommonly the seat of secondary carcinomatous growths. Primary sarcomata also are occasionally met with. The symptoms are pain, usually very severe, localized at one spot in the spine, followed after a time by some excruciation. The tumour projects sooner or later, if the patient survives sufficiently long, into the spinal canal and compresses the cord, causing paraplegia. Except in cases in which the tumour is secondary the diagnosis from dry caries is scarcely possible. Early supervention of paraplegia, with slight excruciation, in a patient past middle life, would, however, suggest the presence of a tumour.

Davies-Colley has recorded a case in which a fibro-sarcoma, growing from the laminae of the fifth and sixth dorsal vertebræ, had, by its pressure on the

cord, produced almost complete paralysis and impairment of sensation in the lower limbs, with paresis of the bladder. Complete recovery followed the removal of the growth.

Caselli successfully removed an osteoma projecting into the spinal canal from the posterior arch of the fifth dorsal vertebra. The symptoms, which consisted of girdle-pains, paresis of the lower limbs, sensory disturbances, and weakness of the bladder and rectum, underwent great improvement after the operation.

**Tumours within the Spinal Canal.**—Tumours within the spinal canal may arise inside or outside the dura mater. Outside the dura mater lipomata are most common, though these are rare. Within the dura mater syphilitic gummata, sarcomata, myxomata, and psammomata are occasionally met with, and fatty tumours have been found in a few cases. The symptoms produced by these growths are those of slow compression of the cord, for which I must refer the reader to works on medicine. If unrelieved by treatment they inevitably cause death, and syphilitic gummata alone are influenced by drugs. Writing in 1886, Gowers suggested that Surgery might ultimately be able to cope with meningeal tumours, those actually implicating the cord being of course beyond the reach of operative interference. In 1887 a middle aged man came under his care with symptoms of a tumour compressing the cord in the upper dorsal region, causing almost complete paraplegia and anæsthesia below the level of the fifth dorsal nerve. On June 9th, 1887, Victor Horsley undertook its removal. The spines and laminæ of the third, fourth, and fifth dorsal vertebræ were cut away, the dura mater opened, and a myxoma removed, which was pressing on the right side of the cord. On January 28th, 1888, the patient was exhibited at the Medico-Chirurgical Society, having completely recovered from all his symptoms except a little stiffness in the legs. The wound was soundly healed, and no artificial support was required.

Since this time several cases have been recorded in which an operation has been undertaken for the removal of tumours within the spinal canal. In Horsley's second case the patient died of shock. The most successful is one by Rehn. In this case a lymphangioma compressing the cauda equina had produced paresis of the lower limbs, bladder, and rectum, with severe pains and loss of knee jerks. The tumour was removed, and the patient recovered power, so that he was able to return to his work. White of New York operated on a case in which paraplegia was thought to be due to an intraspinal tumour; no tumour was found, but recovery followed the removal of some dense tissue around the dura mater and the separation of adhesions within it. Abbe removed a sarcoma from outside the dura mater, but the patient died on the ninth day.

The results thus far obtained certainly justify an exploratory operation when the diagnosis of intraspinal tumour is warranted by the symptoms. Of a series of eight cases, in two the removal of the tumour was followed by cure, in two by death, and in one by recovery without relief; in one case of tumour projecting into the front of the canal, no attempt was made to remove it, but the patient's pain was relieved; of two cases in which no actual tumour was found, one recovered, and the other died.

## CHAPTER LII.

## DISEASES OF BURSE, SHEATHS OF TENDONS, AND MUSCLES.

## DISEASES OF BURSE.

THE bursæ which naturally exist, either under the skin, beneath the muscles and ligaments, or around tendons, are subject to various diseases. These sacs are sometimes developed from continued friction in situations where they are not naturally met with : thus, for instance, bursæ have been found at the projecting point of a hump-back, on the prominent parts of club-feet, or at the extremity of a stump. These abnormal bursæ also may become diseased.

**Situations in which Bursæ exist.**—Bursæ are either deep-seated or subcutaneous. The deep bursæ are as a rule more perfectly developed, closely resembling true synovial sacs, and in many cases communicating with the cavity of a neighbouring articulation. The subcutaneous bursæ, situated over prominent bony points, appear to be little more than enlarged areolar spaces, and are in most places acquired after birth as the result of friction. The following are among the most important situations of the bursæ. On the front of the neck, according to Verneuil, there are three bursæ, one in front of the pomum Adami ; one in the thyro-hyoid space, extending to the under surface of the hyoid bone, beneath the sterno-hyoid muscles ; and another above the hyoid bone between the genio-hyoid and genio-hyoglossus muscles of the opposite sides. Beneath the deltoid and the acromion process is a large bursa, often communicating with the shoulder-joint. In the neighbourhood of the elbow are a large subcutaneous bursa over the olecranon, and a small one between the biceps tendon and the bone immediately above the insertion of the muscle. In the neighbourhood of the hip are three bursæ about the great trochanter : a large one between it and the gluteus maximus, and two smaller sacs between the smaller glutei and the bone. Another bursa of considerable size lies over the tuberosity of the ischium. In front of the joint is a bursa beneath the psoas and iliacus muscles, frequently communicating with the cavity of the articulation. In the neighbourhood of the knee there are three bursæ in front : two over the patella, and one beneath the ligamentum patellæ, between it and the upper part of the tibia. The large bursa patellæ lies beneath the deep fascia, but a smaller one is found over this between the fascia and the skin. Occasionally the upper part of the synovial pouch of the knee is shut off from the general cavity of the joint, and forms a separate bursa beneath the extensors. In the ham there is a large bursa between the semimembranosus and the inner head of the gastrocnemius which frequently communicates with the joint ; a smaller bursa on the outer side, between the outer head of the gastrocnemius and the bone ; another between the biceps tendon and the external lateral ligament ; and others beneath the semimembranosus, the popliteus, and the sartorius, gracilis and semitendinosus—

between these muscles and the bone. At the heel there is a large bursa between the tendo Achillis and the os calcis. The above bursæ are all well-developed and constantly present, and are those most liable to disease; but in addition to these a number of less perfectly formed subcutaneous sacs are met with in all parts of the body. The most important of these are in the following situations:—behind the angle of the lower jaw, on the symphysis of the chin; on the acromion, the external and internal condyles of the humerus, the styloid processes of the ulna and radius; on the dorsal surface of the metacarpo-phalangeal articulations, and on the dorsal aspect of the phalangeal articulations; on the anterior superior spine of the ilium; on each condyle of the thigh-bone, the tuberosity of the tibia, the two malleoli, the dorsal aspect of the toes, and on the plantar aspect of the heads of the first and fifth metatarsal bones.

**Morbid Alterations.**—The continued irritation of bursæ by pressure may cause them to enlarge and to undergo various changes in structure. Enlargement of the bursæ in particular situations is often connected with special employments, by which pressure is exercised upon certain parts of the body: thus frequent kneeling will occasion enlargement of the bursa patellæ, hence called “housemaid’s knee;” miners are subject to an enlargement of the bursa lying over the olecranon, hence called “miner’s elbow” (Fig. 612); and hand-weavers to the same condition in that over the tuberosity of the ischium, giving rise to “weaver’s bottom.”

Fig. 612.—Enlarged Bursa over Olecranon—Miner’s Elbow.

The following pathological conditions may occur in the bursæ in any part of the body:—

1. The bursa may, in consequence of continued pressure or irritation, become simply enlarged and filled by the excessive secretion of a clear straw-coloured serous fluid. This is termed *Dropsy of the Bursa*.

2. Acute inflammation may take place in the bursa with or without previous enlargement. Suppuration often occurs, and when the swelling is opened, fluid, consisting of an admixture of the bursal secretion and pus, escapes. The bursa, when its contents have supplicated, may either give way externally, pointing like an ordinary abscess, and the integuments covering it sloughing; or the pus may escape subcutaneously beneath the deep fascia, and form a widely spreading abscess around the part.

3. The enlarged bursa may contain a dark fluid, usually of a brownish colour, with a large number of small flattened elongated bodies of about the size of grains of rice or of melon-seeds, floating in it. The wall of the bursa is thickened and, according to Nicaise, the presence of tubercle nodules has in some cases been demonstrated in the dense fibroid tissue of which it is composed. The “*melon-seed bodies*” are of a fibroid structure, and their mode of origin is not certain. They have been supposed to be formed in some cases by a fibrinous exudation into the cavity of the bursa, their peculiar form

being the result of the movement of the part. In other cases they have been supposed to arise from villous growths similar to those observed in the synovial membranes of joints. That they may be formed from extravasated blood also seems probable from the fact that Shattock has discovered crystals of hæmatoidin in some of the specimens in the museum of University College. The fluid is sometimes found to contain cholesterine.

4. The wall of the bursa may gradually become thickened by a growth of dense fibroid tissue, until the tumour becomes perfectly solid, or at most contains but a small cavity with a little serous fluid in its centre. The section of a bursa thus solidified presents a laminated or foliated appearance. This condition is in many cases an effect of syphilis.

5. Occasionally in gout, bursæ may become the seat of a deposit of urate of soda. This is most commonly met with in the bursa over the olecranon.

6. In rare instances a gumma may take origin from the wall of a bursa and occupy its interior. Softening occurs, and as the result of ulceration of the overlying tissues sinuses are left leading into the broken down growth.

7. Tuberculous disease of a bursa may result in the distension of the cavity by a mass of pulpy granulation-tissue, which eventually undergoes caseation with the formation of a chronic abscess.

The symptoms of the diseases of bursæ in general will be best studied by considering them as they occur in the bursa patellæ, which, from its exposed situation, and its liability to injury, is more prone to become diseased than any other similar structure in the body. I shall therefore first describe the symptoms and treatment of that bursa, and subsequently briefly allude to the similar morbid conditions in some of those situated in other parts.

**DISEASES OF THE BURSA PATELLÆ.**—The various affections to which the bursa is liable, may be divided into two classes: 1. Acute inflammatory affections; and 2. Chronic enlargements, of a fluid or of a solid character.

1. **Acute Inflammatory Affections.**—This bursa is frequently the seat of **Simple Inflammation**. Undue pressure in kneeling upon a hard, irregular, and cold surface, such as stone, is apt to excite inflammation: hence its frequency in housemaids, whose occupation obliges them to kneel a great deal on floors and stone steps; and hence, also, the common title of "housemaid's knee," given to this and to many other affections of this bursa. But this disease, although frequent among housemaids, is not limited to them; for it occurs in females following other occupations, and in men as well as in women.

In simple inflammation, however occasioned, the bursa becomes rather suddenly swollen, tense, red, and hot, with some fluctuation deeply under the integuments. The swelling, heat, fluctuation, and redness of a dusky colour all situated in front of the patella, indicate the nature of the affection.

The **Treatment** consists in the application of glycerine and belladonna ointment and hot fomentations, and keeping the patient at rest; under this treatment, the disease will usually undergo resolution in a few days. If very acute, two or three leeches may be of service. It may, however, go on to suppuration, and in rare cases, to disease of the patella itself, or sloughing of the bursa.

**Suppuration of the Bursa** occurs in a considerable proportion of cases of acute inflammation, and is a matter of great consequence; because the accumulation of pus, being of large size, and tending to diffuse itself around the knee-joint, is liable to be mistaken for abscess in that articulation. Some-

times it will point, and the pus discharge itself externally in the usual manner; but very generally it gives way subcutaneously, invariably to the outer side of the sac, and its contents speedily diffuse themselves widely around the joint beneath the fascia lata.

The history of the case affords the means of diagnosis. In suppuration of the bursa patellæ, the abscess commences by a superficial swelling and inflammation in front of the knee, which, after a time, extends laterally, enveloping the joint, the fluid gravitating on each side, but more especially externally, nearly as far, perhaps, as the ham-strings. There will have been none of the signs indicative of acute arthritis, no startings of the limb, no laxity or pain in moving the articulation, no grating of the articular ends; and little constitutional disturbance. The movements of flexion and extension of the joint are free up to a certain point, where they are checked by the mechanical obstacle of the purulent accumulation. But the most important diagnostic sign is the relation of the abscess to the patella. In a suppurating bursa, the patella is invisible, being covered by the fluctuating swelling; in effusion, whether serous or purulent, into the joint, the patella is above, floating upon the fluid.

In the **Treatment** of this condition the pus must be let out by a free incision, if possible before the abscess has extended beyond the limits of the bursa. The incision is usually made in the middle line, but better drainage is obtained, and the scar over the patella avoided if the incision be made at the outer side. To do this, a very small puncture may be made in front, and a probe introduced, the point of which may be made to project at the outer limit of the cavity. The probe may then be cut down upon, the cavity well flushed out with 1 in 1000 solution of perchloride of mercury, and a drainage-tube introduced, the anterior puncture being allowed to close. If the abscess be of considerable size, an incision must be made on each side, care being taken not to cut so deeply as to injure the capsule of the joint. If antiseptic precautions are taken, it is necessary only to make an opening of sufficient size to admit a drainage-tube, but under other circumstances, the incision must be much more free. The burrowing beneath the fascia lata that not unfrequently follows abscess of the bursa patellæ, is due first, to not opening early enough; secondly, to insufficient drainage; and thirdly, to decomposition of the discharges, and cannot be regarded as an unavoidable accident.

**Disease of the Patella.**—Sometimes, but very rarely, abscess of the bursa patellæ will give rise to caries of the patella, but so far as my experience goes this is exceedingly rare. I had one case under my care in the Hospital. The patient was a woman, and when admitted, she had several sinuses on the fore part of the knee-joint, through which the probe led down to a rough and carious patella. It was ascertained that she had had "housemaid's knee," which had run on to suppuration, but that the abscess had never been freely laid open. The joint itself was unaffected. I laid open the sinuses, and, finding the anterior surface of the patella soft and carious, removed the diseased part of the bone with the gouge. About three weeks after this, the joint became suddenly swollen, and evidently filled with pus, so that it was necessary to remove the limb above the knee. After amputation, it was found that the disease had perforated the patellar cartilage, by a small aperture, and had thus given rise to suppuration within the joint.

**Sloughing of the Bursa Patellæ** occasionally occurs as the result of its inflammation and suppuration. A woman was admitted into the Hospital, in

whom this bursa had suppurated; and not only the bursa but also the integuments covering it had sloughed away, leaving a circular ulcer as large as the palm of the hand, having a flabby surface, and undermined, purple edges. The patella was not exposed. Under ordinary treatment, the ulcer slowly healed.

2. **Chronic Enlargements.**—In the second variety of disease of the bursa patellæ there is enlargement of the bursa without evident signs of inflammation, owing to the accumulation within it of bursal fluid, or of this fluid mixed with solid bodies, or of solid fibroid deposits.

**Simple Enlargement, or Dropsy of the Bursa,** is an accumulation of clear serous fluid within it. Repeated pressure, as in kneeling, is the common cause of this affection; hence it frequently occurs in housemaids, and constitutes the true "housemaid's knee." But it is also common in other people, whose vocation necessitates long-continued kneeling. One case of the affection in University College Hospital was that of a carpet-layer, a man aged thirty, who, in consequence of habitually kneeling upon the left knee in laying down carpets, had a tumour there as large as an orange, indolent, soft and fluctuating—evidently an enlarged bursa.

The **Treatment** of these tumours is very simple. If the effusion has taken place somewhat rapidly, and distinctly in connexion with an injury, the application of tincture of iodine, or a blister, will induce the absorption of the fluid. When the disease is more chronic, these measures usually fail. The fluid may then be withdrawn by means of the aspirator and pressure applied with an india-rubber bandage. If this fail, antiseptic drainage should be tried. A small puncture is made, and a drainage-tube inserted with all antiseptic precautions. In many cases drainage for a week or ten days will suffice to correct the tendency to over-secretion without any inflammation or suppuration being set up. The result is, however, made more certain by exciting a slight degree of simple inflammation by injecting the cavity at the time the tube is inserted with carbolic acid lotion (1 in 20), or solution of chloride of zinc (20 gr. to 3j), or tincture of iodine. Should this also fail the sac should be dissected out in the same way as a solid bursa.

**Chronic Enlargement with Melon-seed bodies.**—This affection is closely allied to the last, and appears to be an advanced degree of it. It consists in a chronic enlargement of the bursa, the coats of which are more or less thickened. The contents of the enlarged bursa consist of a dark fluid, in which float a number of smooth oval bodies, of the size and shape of melon-seeds. I have seen this condition both in the male and in the female. It may be distinguished from simple enlargement of the bursa, by the peculiar crackling sensation which is communicated to the hand when the tumour is manipulated. This arises from the melon-seed bodies floating about and rubbing against each other. Most probably some of these cases are tuberculous as in the similar conditions in the sheaths of tendons, but tuberculous disease is certainly rare in the bursa patellæ.

The **Treatment** consists in making an incision free enough to allow the melon-seed bodies to pass out. The cavity may then be syringed out with carbolic or mercurial lotion, to ensure the removal of all the solid bodies; a drainage-tube is then inserted and retained for a week or ten days, the wound being treated with some form of antiseptic dressing. If the wall be much thickened the whole bursa should be dissected out.

**Solid Tumours** of the bursa patellæ are by many supposed to be the

result of a deposition of fibrin gradually taking the place of the fluid of an ordinary "housemaid's knee," and which, instead of taking the form of melon-seed bodies, is deposited in concentric layers. This has not been the case, however, in the specimens which I have seen. In these there has always been a true fibroid growth in the wall of the bursa from the very first; the tumour was never fluid, but hard and solid from the commencement, and continued slowly to augment in size, until it occasioned sufficient inconvenience to require removal. In some cases there has been a previous syphilitic taint. The patient complains of pain in the tumour like that which is experienced in nodes, and it is by no means impossible that there may be always a syphilitic origin for these tumours. However that may be, in the cases that have fallen under my observation, the tumours have never been fluid, nor have they originated in pressure, but appear to have been primary growths of fibroid matter.

Fig. 612.—Very large solid tumour of the bursa patellae. Both knees were similarly affected.

*Treatment.*—There is nothing to be done with such tumours but to dissect them out. With ordinary care the joint runs no risk; but as the deep fascia is necessarily opened up, widely spreading suppuration may occur beneath it, unless good drainage and perfect asepsis be maintained. In order to provide more efficient drainage, it is better to remove the bursa by a curved incision on the outer side of the tumour rather than by one in the middle line.

**DISEASES OF OTHER BURSAE.**—The diseases of the Bursa Patellæ being taken as the type, the affections of the other more important bursæ require to be but briefly alluded to.

**Enlargement of the Pre-hyoidean bursa** or of that between the genio-hyoid muscles occasionally forms a thin-walled fluctuating tumour in the front of the neck and beneath the chin. When the bursa between the genio-hyoid muscles is the seat of disease, the cyst may push up into the floor of the mouth between the genio-hyoglossi. When the pre-hyoidean bursa is affected the cyst tends to extend downwards over the larynx, forming one of the varieties of the so-called "hydrocele of the neck."

*Treatment.*—These cysts can usually be cured by tapping, with injection of chloride of zinc or tincture of iodine, followed by antiseptic drainage. The walls are too thin and their attachments too deep to make it advisable to attempt their removal by dissection.

The **Bursa beneath the Deltoid** is not uncommonly enlarged. The affection assumes most frequently the form of simple chronic enlargement with or without the presence of melon-seed bodies. It forms a rounded swelling, causing prominence of the deltoid, with distinct fluctuation. In some cases enlargement of this bursa is connected with chronic tuberculous disease of the shoulder-joint, which should always be carefully looked for. The *Treatment*, if the joint be not diseased, consists in aspiration and blistering

Should this fail, or should the soft crackling on movement show the presence of melon-seed bodies, an incision may be carefully made at the most convenient spot, and the sac emptied and drained. This operation must not be undertaken without due consideration, and must be performed with the strictest antiseptic precautions, as the bursa frequently communicates with the articular cavity, and any septic process occurring in it would certainly lead to destruction of the shoulder-joint.

**The Bursa over the Olecranon.**—Inflammation of this bursa ending in suppuration is a common result of falls on the elbow, with or without a wound. It causes severe pain and redness, with œdema extending a long way above and below the joint. The pus may burrow some distance down the forearm unless sufficiently free incision be made early. The inflammation very rarely extends to the elbow-joint, but superficial necrosis of the olecranon sometimes occurs. Chronic enlargement with some thickening of the walls forms the affection known as "miner's elbow." Solid tumours of the bursa are rare. It is not uncommon to find the bursa the seat of gouty deposits. The *Treatment* of these affections is conducted on exactly the same principles as that of the corresponding conditions at the knee.

**The Bursa about the Trochanter Major** are occasionally the seat of chronic inflammatory enlargement or dropsy, and of acute inflammation terminating in suppuration. The latter condition is of great importance from its simulating hip-disease, or sometimes causing it by implication of the joint. The diagnosis can be made only by observing that the characteristic deformity of the hip is absent, and on opening the abscess the finger will not be able to detect either diseased bone or any connexion with the joint. The treatment is conducted on ordinary principles.

There can be little doubt that the following case was one of tuberculous disease of the bursa beneath the insertion of the gluteus maximus. A boy, ten years of age, bruised his left hip in a fall. About a month later there was a deep fluctuating swelling in the outer side of the thigh in the upper third. No thickening of the great trochanter could be detected, and there were no signs of hip disease. The patient's death was caused by a tuberculous tumour of the cerebellum, symptoms of which had existed for nearly a year. At the *post-mortem* examination a chronic abscess was found beneath the fascia lata; it extended upwards beneath the insertion of the gluteus maximus into the fascia to the situation of the bursa between that muscle and the trochanter. Here there was a softening cheesy mass about an inch in diameter and a quarter of an inch thick.

The bone was carefully examined, but appeared to be quite free from disease. The treatment of such a condition should consist in freely opening and scraping the abscess, before the disease has involved the subjacent bone or neighbouring joint.

**The Bursa over the Tuberosity of the Ischium** is sometimes enlarged, forming the condition termed "Weaver's bottom." The enlargement is often solid, and may cause great discomfort in sitting. Under these circumstances it may be safely removed by the knife. It will be found to be in part deeply seated under the lower part of the gluteus maximus. It is not clearly circumscribed, its outer wall being continuous with the surrounding fat. There may be rather free bleeding, but this is easily arrested.

**The Bursa beneath the Psoas** is rarely enlarged, but cases have been

recorded in which fluctuating tumours, containing serous fluid, have been met with in the groin, and have been supposed to have arisen in this way. These tumours are deeply seated, and closely resemble psoas abscesses; whilst the flexion of the thigh, which relieves the tension of the swelling, may suggest the existence of disease of the hip-joint. The true nature of these swellings can be ascertained only by the use of the aspirator. They must be treated on the principles already laid down. The frequent communication of this bursa with the hip-joint must be borne in mind; it probably explains the occasional invasion of the joint by a psoas abscess, and *vice versa*, the formation of a psoas abscess as a result of disease of the joint.

The **Bursæ in the Ham**, especially that between the inner head of the gastrocnemius and the semimembranosus not unfrequently become enlarged. Their walls become slightly thickened, but melon-seed bodies or solid enlargement are rare. The distended bursa forms a fluctuating swelling, which becomes tense during extension of the joint and lax during flexion. There may be some slight pulsation communicated from the popliteal artery, and the swelling may thus resemble an aneurism, but the pulsation is not expansile, and the tumour does not diminish in size on compressing the femoral artery. Sometimes by firm pressure the cyst may be made partially to empty itself into the knee, the signs of fluid in the joint then becoming apparent. These enlarged bursæ in the ham usually cause but little pain. The skin covering the swelling is normal in appearance. The *Treatment* must be conducted with caution, owing to the close proximity, if not actual communication, of the bursal tumour with the joint. In many cases a cure can be obtained by fixing the knee with a splint or in plaster of Paris, producing counter-irritation with blisters or iodine, and then applying an elastic bandage. If this fail, aspiration followed by pressure may be tried; if that is not successful, injection with iodine may cure the disease. With strict antiseptic precautions, drainage or excision may be practised in cases resisting the simpler methods of treatment. The risk of drainage is that a sinus may persist, through which the knee-joint is likely to become infected. In excising these bursæ—and it is the large one on the inner side which has chiefly been treated in this way—the cyst should be separated as completely as possible, and the pedicle ligatured with silk before it is divided.

The **Bursa beneath the Tendo Achillis** at the heel is sometimes diseased. It forms a fluctuating swelling on each side of the tendon, and may simulate disease of the ankle-joint. The treatment presents nothing peculiar.

**Bunion. Hallux Valgus.**—When the bursa which lies towards the plantar surface of the head of the first metatarsal bone becomes enlarged, or when a new sac is formed upon the inner aspect of the bone, the disease termed a *bunion* occurs. The enlargement of the bursa is usually secondary to an alteration in the shape and position of the great toe. The displacement takes place at the metatarso-phalangeal joint, the great toe lying over or under the contiguous toes, and a prominent angle being formed between the metatarsal bone and the phalanx (Fig. 614). In the majority of cases the deformity is the result of the pressure of narrow-pointed boots; in some instances it is due to arthritis deformans, with alteration in the shape of the bones. The skin covering the prominent metatarso-phalangeal joint becomes thickened, and the bursa which is there naturally becomes enlarged, or an adventitious one forms. As the result of repeated irritation, acute inflam-

mation and suppuration are liable to occur, and often an indolent sinus discharging thin unhealthy pus is left.

**Treatment.**—The first thing to be done is to relieve the pressure on the part by wearing properly shaped boots, made with the inner side of the sole straight from the toe to the heel. If accidental inflammation be excited in the part, it must be allayed by the use of warm foot-baths, and fomentations; the cutaneous irritation that is left may best be removed by painting the surface with a strong solution of nitrate of silver. An attempt may be made to rectify the faulty direction of the toe by using a contrivance (Fig. 615), the action of which consists in drawing the toe inwards by means of a slender steel spring, or by moulding a leather or gutta-percha splint to the inner side of the foot. Should these means fail, the position of the toe may be remedied by the division of the external lateral ligament of the metatarso-phalangeal articulation, or of the tendon of the adductor hallucis, and of the

Fig. 614.—Hallux Valgus and Bunion.

Fig. 615.—Apparatus for Deformity of Foot as in Fig. 614.

inner head of the flexor brevis hallucis; the toe, when restored to its position, being for a time kept fixed upon an under-splint.

As these methods of treatment are, however, seldom successful, it was suggested by C. Hoar to perform antiseptic osteotomy of the metatarsal bone of the great toe through the neck of the bone. This operation has been most successfully performed by A. E. Barker. A small wedge-shaped piece was removed from the inner side of the metatarsal bone, and by fracturing the remainder, the toe was brought at once into good position.

Occasionally suppuration extends from the bursa to the metatarso-phalangeal joint, which becomes more or less extensively disorganized. In elderly feeble patients this condition is very serious as a sloughing inflammation may be set up in the foot which may terminate fatally. If the patient's condition admit of it, amputation should be performed, after which the ulcerated head of the metatarsal bone will usually heal without difficulty. In younger persons the toe may sometimes be saved by excision of the joint, the enlarged and suppurating bursa being removed at the same time.

## DISEASES OF SHEATHS OF TENDONS.

The synovial sheath of a tendon is liable to acute and chronic inflammatory conditions which in many respects resemble the affections of the synovial membrane of joints. Certain cysts known as "ganglia" also arise in connexion with tendon sheaths. The tendons of the hand are most liable to these affections.

**ACUTE TENO-SYNOVITIS.**—Acute inflammation of the sheaths of tendons is usually the result of a strain or other slight injury. It is especially apt to occur in rheumatic and gouty subjects, sometimes without any obvious exciting cause. Acute teno-synovitis is especially common in the extensor tendons at the wrist, as the result of strains or twists of the hand; it is very common in the extensor muscles of the thumb from feathering the oar in rowing. The tendon of the long head of the biceps may be affected. In this affection there is swelling of a puffy character, with tenderness when the part is pressed on or moved. Usually a peculiar fine crackling sensation is communicated to the Surgeon's hand when he examines the affected part, caused by the presence of slight effusion into the inflamed sheath.

The **Treatment** consists in fixing the part by the use of a splint and applying glycerine and belladonna with hot flannel fomentations. This treatment may be followed by the application of gentle pressure by means of a bandage. Should the condition tend to become chronic the application of blisters or the mercury and ammoniacum plaster will be found very useful.

**CHRONIC TENO-SYNOVITIS.**—This condition, which is often spoken of as "*compound ganglion*," consists in a chronic effusion into the sheath of a tendon without any manifest signs of inflammation. It is analogous to chronic synovitis of a joint. The sheath is often thickened as well as dilated, and the contained fluid is clear and yellowish in colour. In some cases the sheath itself is very vascular, and lined by a red, fringed, and velvety membrane; the fluid may then be dark and bloody, and contain masses of buff-coloured fibrin or a large number of "melon-seed bodies," like those met with in certain forms of bursæ.

In two cases Nicaise has demonstrated the presence of tubercle nodules in the diseased synovial membrane, and it is now generally believed that, in many cases at least, this condition is **tuberculous**; the changes are strictly analogous to those found in the variety of tuberculous joint disease known as "tuberculous hydrops" (p. 346).

Tuberculous inflammation of a tendon sheath may also occur in a form similar to that usually met with in joints. The sheath becomes distended with pulpy granulation-tissue which may undergo caseation with the formation of chronic abscess.

**Symptoms.**—Chronic teno-synovitis is met with chiefly in the palm of the hand, but it has been observed on the dorsum, sole or inner side of the foot. The swelling may attain a considerable size, and then usually becomes irregular in shape, owing to several sheaths being affected. When the common sheath of the flexor tendons of the fingers is distended by a chronic effusion, the swelling projects above and below the anterior annular ligament of the wrist, which forms a transverse groove on its surface. Chronic teno-synovitis at the wrist may be the first indication in some cases of disease of the bones of the carpus, as the sheaths come into close contact with the

bones. In a case in University College Hospital, the "compound ganglion" which contained melon-seed bodies was apparently cured by antiseptic drainage. Some months later caries of the carpus manifested itself, necessitating excision of the wrist-joint.

The fungating form of tuberculous disease gives rise to an elongated pulpy swelling in the position of the affected sheath, followed by the formation of a chronic abscess.

The **Treatment** of chronic teno-synovitis should consist in the first place in perfect rest of the affected part, and counter-irritation by blisters or iodine. I have sometimes succeeded in curing this disease at the wrist by the injection of a small quantity of tincture of iodine through a small opening in the palm. The most efficient method, however, consists in antiseptic drainage, a small tube being inserted above and below the annular ligament. If the sheath contain melon-seed bodies and is lined with a pulpy layer, or if it is completely filled with tuberculous granulation-tissue, a free incision must be made into the sheath and the diseased tissue removed by scraping and dissecting. In the case of the common flexor sheath at the wrist, this procedure may necessitate division of the annular ligament, which should afterwards be sutured. After the operation the hand must be fixed on a splint with the fingers slightly flexed so that any resulting adhesions may be broken down.

**SIMPLE GANGLION.**—This consists of a cyst varying in size from a cherry-stone to a large marble, and containing sometimes a clear transparent fluid of a yellowish colour, but more commonly a pinkish or yellowish gelatinous substance. It occurs as a smooth, globular, elastic, and tense tumour, usually situated on the back of the wrist, where it forms a distinct round projection; it may occur also on the dorsum of the foot. In both situations it is often distinctly connected with the sheaths of the extensor tendons. As the ganglion increases in size, it often gives rise to painful sensations in the parts below it, by pressing upon the neighbouring nerves: thus, a ganglion at the back of the wrist often produces pain and weakness in the hand, by compressing some of the branches of the radial or ulnar nerve which are stretched over it.

Ganglion is by far the most common of all the tumours that occur on the hand. In all cases of oval or rounded, smooth, elastic tumour on the hand or fingers, whether painful or not, ganglion should always be suspected.

A small, hard, and painful ganglion, varying in size from a pin's head to a cherry-stone, is met with in connexion with the flexor tendons of the fingers, usually on the proximal phalanx. If it interferes seriously with the use of the fingers, it may be dissected out.

The mode of origin of a simple ganglion is very doubtful. Paget looks upon it as a cystic transformation of the cells enclosed in the fringe-like processes of the synovial membrane lining the sheath of the tendon. Billroth believes it commences as a pouch-like protrusion from the sheath, the neck of which becomes gradually narrowed till at last a separate cyst is formed lying on the sheath, but not communicating with it. It is often impossible by dissection to prove that a simple ganglion at the wrist has had its origin in a tendon sheath, and indeed there is reason to believe that in some instances the cyst has arisen in connexion with the synovial membrane of the wrist or one of the carpal articulations, probably as a protrusion through the capsule. Ganglia are more common in females than males, and in some instances appear to arise after a strain or other slight injury.

**Treatment.**—When the ganglion is small, as on the back of the wrist, it may commonly be got rid of by being ruptured by forcible pressure with the thumb, or by a sharp blow, or by being tightly compressed by means of a coin wrapped up in lint, and firmly strapped upon the swelling. If it do not disappear in this way, the best plan is to puncture it subcutaneously by means of a valvular opening, to squeeze out its contents, scarify the interior of the cyst, and employ pressure. If the ganglion give rise to much pain and weakness, and cannot be made to disappear by the use of the means just indicated, it may usually be very conveniently and safely obliterated by passing two threads of carbolised silk or horse hair through it, dressing it antiseptically, and leaving it in for four or five days, until sufficient inflammation has been induced for the obliteration of the cyst. Should these means fail, it may be dissected out—a procedure which is attended with some risk of inflammation extending up the sheath of the tendon, unless perfect asepsis is maintained. I have on several occasions performed this operation, without any troublesome consequences ensuing.

**Cartilaginous Tumours** are occasionally met with in connexion with the sheaths of tendons. A specimen of this nature is preserved in the Museum of University College. It consists of numerous small lobules of hyaline cartilage enclosed in a fibrous capsule. It was removed by Marcus Beck from the palmar aspect of the index finger of a young woman; the tumour was firmly adherent to the sheath of the tendons, which was not opened, however, during the operation.

#### DISEASES OF MUSCLES.

The voluntary muscles are not often the seat of primary disease of any kind. **Fatty Degeneration** of muscle, as met with in surgical practice, is usually the result of want of use. In such cases, the muscular fibres are merely atrophied, and the fat, which resembles normal adipose tissue, is accumulated between them. Such a condition is recovered from if the cause of the want of use be removed. True fatty degeneration, in which the protoplasm of the muscular fibres undergoes conversion into fat-granules, is not common in the voluntary muscles, except as a result of complete separation from a healthy nerve centre. **Inflammatory Affections** are usually secondary, the muscle being implicated by extension from surrounding parts. Diffuse inflammation of the voluntary muscles with disseminated abscesses has been observed in pyæmia. Abscesses, as we have already seen in psoas abscess, may enter the sheaths of muscles and cause considerable destruction of tissue. “**Rheumatic inflammation**” of muscles is met with as lumbago, intercostal rheumatism, &c., but of the exact nature of the process we know little.

**Myositis Ossificans** is a rare affection characterized by a gradual and progressive development of bone in the muscles. A skeleton from a case of this disease is preserved in the Museum of the College of Surgeons, whilst amongst recorded cases may be mentioned those of Cæsar Hawkins, Helferich, Godlee, Lendon of Adelaide, and Sympton of Lincoln. The ossification occurs in the connective tissue between the muscle fibres, which undergo atrophy. **Myositis ossificans** is a disease of early life; according to Stonham commencing often between two and three years, and in the majority of cases before fifteen. There is, however, no evidence of heredity in the recorded cases. The disease

occurs chiefly in males, and there is some reason for thinking that it is rheumatic in nature. The muscles chiefly affected are the latissimus dorsi, trapezius, and rhomboids. These become converted into flat bony sheets, and the disease slowly extends to the neck muscles, the shoulder muscles and pectorals. The upper limbs are more extensively affected than the lower. In some cases the tendency to bone formation has been further shown by ossification of ligaments and the formation of exostoses on the bones. The abdominal muscles and the diaphragm usually escape. The general health is unaffected, and the patient may live for many years, becoming gradually more and more crippled by the fixation of the limbs, and dying eventually from interference with the breathing and resulting chest complications, or from the effects of extensive bed-sores. No treatment is of any avail.

Although the widespread ossification of muscles above described is very rare, small bony deposits are not very unfrequently met with in muscles or their tendons as the result of repeated injury. As examples of this may be mentioned the "rider's bone," which forms in the upper part of the adductor muscles of the thigh, and the "drill bone" of the old Prussian soldiers, which formed in the lower part of the deltoid from repeated sharp blows in musket exercise.

**Syphilitic Disease of Muscles** has already been described (Vol. I., p. 1161). It occurs as diffuse sclerosis of the muscle or as gummata. Gummata have been met with in the triceps, vastus externus, sterno-mastoid, gastrocnemius, and many other muscles, but especially in those of the tongue. They grow slowly, infiltrate surrounding parts, and soften if not relieved by treatment. They are not unfrequently multiple. They are accompanied by aching pain, and stiffness of the affected muscle. They derive their importance chiefly from their resemblance to some of the tumours to be immediately described, which has occasionally led to their being cut out. The diagnosis is effected by the history of syphilis, the slow growth and hardness of the tumour, its subsequent softening, and the pain at night. They disappear or diminish rapidly under iodide of potassium.

**Tumours of Muscle.**—Primary tumours of muscle are not common. The growths met with are the various forms of sarcoma, sometimes containing much fibrous tissue (fibro-sarcoma), sometimes soft (round-celled or spindle-celled sarcoma), chondromata, myxomata, fibromata, nævoid growths, and parasitic cysts. Primary carcinoma of muscle never occurs. Teevan collected with much industry the particulars of 62 cases of tumours of muscles of all kinds: about one-third of these were soft sarcomata, 16 were described as fibrous, 8 cystic, 5 hydatid, and 5 nævoid. Malignant sarcomata are most common, according to my experience, in the lower limb. When the upper limbs are affected, the muscles that have, according to Teevan, been most frequently attacked are the pectoralis major, deltoid, and biceps. The muscles of the trunk and neck are seldom diseased, with the exception of the rectus abdominis, which appears to be very liable to tumours.

By far the most common parasitic cyst found in muscle is the ordinary hydatid, of which three cases are recorded below. The *cysticercus cellulosæ*, or hydatid form of the *tænia solium*, has occasionally been met with, and forms a small transparent bladder situated among the muscle fibres. A specimen of this nature, which was examined by Cobbold, is preserved in the Museum of University College. Lastly, the muscles are occasionally infested by the

*trichina spiralis*, the embryos of which become encysted in the interior of the muscle fibres. The cysts, which appear as minute white oval spots, were first discovered by Paget in 1834. The muscles chiefly affected are the diaphragm, the intercostals, and those of the neck and larynx.

Of twelve consecutive cases that I have had under my care in which tumours of different kinds developed primarily in muscular tissue, the following are the particulars. The first case was that of a woman about 48 years of age, in whom a fibro-cystic tumour, as large as a cocoa-nut, developed in connexion with the tensor vaginæ femoris, forming a large mass, which I easily dissected out. The second case was that of a lad about 18, in whom a thick-

Fig. 616.—Fibro-Sarcoma of the Sartorius Muscle.

Fig. 617.—Back View of Tumour, showing Sartorius Muscle.

Fig. 618.—Front View of Tumour, laid open and showing Sartorius, &c.

walled cystic tumour, as large as a foetal head, and containing clear fluid, developed in the substance of the adductor brevis, from which it was dissected out with no little difficulty, and with a fatal result. The third case was that of a man from whom the accompanying drawings are taken (Figs. 616, 617, 618), in whom a fibro-sarcoma developed in the substance of the sartorius muscle of the left thigh, in consequence of a strain. After growing slowly for about six years, it had attained the size of a child's head, when I removed it, together with seven or eight inches of the muscle from the inside of the sheath of which it had originated. The sheath of the femoral vessels, which was exposed for a considerable extent, was unaffected by the disease. Recurrence took place in less than twelve months in the cicatrix, and when the secondary

tumour had attained the size of an ostrich's egg, it was removed, the patient making a good recovery ; but the disease again returned, and eventually proved fatal. The fourth case was that of a man aged about 40, in the sole of whose foot a cystic tumour, about as large as a goose's egg, developed from the flexor brevis digitorum. This was carefully dissected out ; but in a few months the patient returned, with a solid, elastic, rapidly growing tumour, evidently a sarcoma, developed in the cicatrix (Fig. 619). The foot was amputated, and on section the mass proved to be a soft sarcoma, and to have developed from the muscular structure just named (Fig. 620).

In three cases the tumours were hydatid. In one patient, a young woman, the disease was seated in the deltoid ; in another, a medical man, about 50

Fig. 619.—Sarcomatous Tumour in Sole.

Fig. 620.—Section of Foot, showing situation of Tumour.

years of age, in the outer edge of the latissimus dorsi ; and the third in a gentleman about 60 years old, in the biceps. In each of these cases, the tumour was successfully excised.

In the eighth case the tumour was a chondroma in the tibialis anticus. I have seen two other cases of chondroma in muscles : one situated in the vastus externus of the thigh : the other in connexion with the pectoral muscle. The ninth case was a sarcoma of the rectus femoris in a man aged 21, which I excised ; the tenth, a malignant growth in the anterior abdominal wall in an elderly gentleman ; the eleventh, a soft sarcoma of the muscles of the calf in a middle-aged lady, for which amputation was practised ; and the twelfth, a sarcoma of the forearm in a lad.

Tumours developing primarily in the intermuscular areolar planes are of common occurrence ; but these are very different from, and must not be confounded with, true tumours of muscle.

The *Treatment* of these various muscular tumours must be considered on ordinary surgical principles. When of an innocent character, as cystic or hydatid, fibrous, nævoid, or cartilaginous, they may be dissected out from the muscular tissue amongst which they lie, and no fear of recurrence need be entertained.

When they are malignant, amputation of the limb, if the tumour be favourably situated for such an operation, is generally the only resource: partial operations are usually worse than useless, as they are followed by a speedy recurrence. Teevan made the ingenious suggestion of applying to malignant tumours of muscle the same rule of practice that guides us in operations on bones similarly affected; viz., to remove the whole of the organ that is the seat of disease, excising the entire muscle from its origin to its insertion, and thus eliminating from the system the whole of the disease, which will be confined within its sheath—a structure that for a long time resists the outward pressure of a new growth. The suggestion is founded on correct pathological principles: the only objection to it is the difficulty of applying it in actual practice—there being few muscles so situated that they can with safety be completely extirpated.

## CHAPTER LIII.

## DEFORMITIES.

## LATERAL CURVATURE OF THE SPINE. SCOLIOSIS.

THE normal erect position of the spinal column, and the various curves which it presents, are maintained by the close manner in which its separate elements are knit together by ligamentous and muscular structures, and by the way in which, when thus bound together as a whole, it is supported on each side by the strong mass of the erector spinæ and its prolongations. The abnormal curvatures of which the spine may be the seat are either lateral or antero-posterior in their direction, and the complicated character of the curves receives its explanation from the fact that when an antero-posterior or lateral deviation occurs in any situation, secondary deviations are produced

Fig. 621. — Double Lateral Curve.

Fig. 622. — Quadruple Lateral Curve.

Fig. 623. — Kyphosis.

Fig. 624. — Lordosis.

in other regions in order that the erect position of the spine as a whole may be maintained.

Lateral curvature, with which we are here chiefly concerned, is often spoken of as **Scoliosis** (Figs. 621 and 622). In some rare cases, however, independently of disease of the vertebræ, the lower portion of the cervical or the upper dorsal region projects backwards in an arched manner, constituting the condition termed **Kyphosis** (Fig. 623); and in other cases, of still less frequent occurrence, there may be incurvation of the spine in the dorso-lumbar region, giving rise to **Lordosis** (Fig. 624). Although lordosis is rare as a primary deviation of the spine, it is a frequent result of the tilting for-

wards of the pelvis, which so frequently occurs in cases of flexion of the hip-joint from disease (see p. 417).

LATERAL CURVATURE OF THE SPINE may conveniently be divided into two classes—first, those cases in which the deformity is the primary condition; and secondly, those in which the deformity is secondary to, or symptomatic of, some other affection.

**Primary Lateral Curvature** commences most commonly at an early period of life, usually between the ages of twelve and eighteen—seldom before the one, and not very commonly after the other. It is occasionally met with in rickety children. Girls are much more frequently affected than boys. The onset of the deformity is especially frequent about the age of puberty; at a time of life when the tonicity of the muscular system not unfrequently becomes lessened by the occurrence of anæmia and those states of impaired health that so frequently attend the establishment of the uterine function; and before the osseous structures of the body are fully developed. At this period of life, also, it frequently happens that the spine becomes rather suddenly elongated by a rapid increase in growth; or that it becomes overweighted by the body developing, and the shoulders and bust becoming unduly stout and expanded. A tendency to deviation of the spine is extremely common about this age, and if this tendency be increased by injurious habits, amongst which are all one-sided postures in which the body is twisted, as in playing certain games, some musical instruments, or in leaning over a table in drawing and writing, it may rapidly increase until it assumes the true characters of lateral curvature. Associated with the deviation of the spine, flat-foot and knock-knee are not uncommonly met with. Lateral curvature is common also in young women of a short and thick build, in whom the bust and shoulders become largely and early developed. In them too great a weight is thrown on the spine before its osseous and ligamentous structures are sufficiently developed and solidified to enable it to support this burden. Amongst the more common predisposing causes must undoubtedly be reckoned the sedentary occupations and enervating habits commonly encouraged in girls in the wealthier ranks of life, which, by preventing due muscular development, at the same time that they induce a general loss of tone in the system, may directly occasion the disease. In growing lads, lateral curvature may be produced by a habitually maintained faulty position, as in sitting too long at the desk, or in following certain occupations. The deformity is undoubtedly due in many cases to the habitual carrying of heavy weights by growing girls with weak spines. An inequality in the focal length of the two eyes is a common cause of spinal curvature, the patient habitually twisting the body forward on the side of the defective eye, so as to endeavour to accommodate the vision of it to that of the stronger one. That the real cause of lateral curvature of the spine is to be found in faulty habits of life, and not in sex, is evidenced by the rarity of the affection amongst girls of the labouring class, as compared with its frequency amongst those of the wealthier orders of society.

The causes of the antero-posterior curves are usually to be found in some faulty habits of the patient: either giving rise to an habitual stoop, and thus causing kyphosis, or throwing too great a weight on the loins, and thus giving rise to lordosis. Myopia and other impairments of vision causing the person so affected to stoop, in order to bring the page nearer the eye in

reading, is a common cause of round shoulders, and in more extreme degrees, of kyphosis.

**Mechanism and Pathology.**—The proper tension of the ligaments and muscles of the spinal columns is necessary for it to maintain the weight of the upper part of the body. If from any of the above causes these structures are weak, and the spine is habitually held in a faulty position, a gradually increasing curvature will develop. The direction of the deviation is often an exaggeration of the normal curves: thus in *kyphosis* the excursion takes place in the lower cervical and upper dorsal regions, which are naturally prominent; and, in *lordosis*, the incurvation is most marked in the lumbar region. In *lateral curvature*, the most marked deformity is in the dorsal region, where the convexity is usually directed to the right, and is indeed an exaggeration of the slight inclination of the spine in the same direction which is so frequently present. A second, or compensating, curve occurs in the lumbar region, and takes a direction opposite to that in the dorsal region (Fig. 621). In some instances there is a quadruple curve (Fig. 622).

Fig. 625.—Lateral Curvature and Rotation of Spine.

At the same time that these lateral curves take place, there is a tendency to rotation of the vertebrae in such a way that the body of each vertebra is directed towards the convexity of the curve, and the spinous process towards the concavity. Thus in most cases the body of a dorsal vertebra looks forwards and to the right, and the spinous process backwards and to the left (Fig. 625). This rotation is of much importance, as we shall see, in the production of the peculiar deformity of the chest which occurs in cases of lateral curvature.

Many explanations have been suggested for the movement of rotation, but in lateral curvature produced in the way above described it seems probable that the rotation is due to the fact that the bodies of the vertebrae are more free to move than the posterior arches, which are bound firmly together by muscles and ligaments. Thus, when lateral curvature occurs, the bodies undergo displacement more readily than the arches, and rotation in the direction above indicated is the result.

Arbuthnot Lane, who has paid much attention to this subject, has shown how lateral curvature may result from the constant assumption of positions of rest in standing. Supposing a feeble subject to stand habitually with the weight thrown on the right lower limb, the pelvis will be tilted so that the upper surface of the sacrum is directed somewhat to the left. A lumbar curve is thus produced having its convexity in the same direction, and a compensating curve with its convexity to the right forms in the dorsal region. In an erect column each vertebra is capable of rotation around an antero-posterior or a transverse axis, but in lateral curvature rotation takes place around an oblique axis directed forwards, outwards and downwards. This is readily

accounted for by the oblique position assumed by the sacral facet when the weight of the body is thrown unequally on the two lower extremities.

In the earlier stages of lateral curvature the bones are not altered but the intervertebral discs are compressed on the concave side of the curve. Soon, however, a gradual alteration takes place in the bones themselves, the bodies of which assume a more or less pronounced wedged shape, the broader end of the wedge corresponding to the convexity and the narrower end to the concavity of the curvature. In advanced cases bony lips are found along the borders of the bodies in the positions of greatest compression, and these may increase in size until, by their union with those of adjacent vertebræ, they form strong buttresses passing from one bone to another. Too much importance cannot be attached to these secondary bony deformities, for the object of treatment must be to cure the curvature before it is rendered permanent by their occurrence.

In the true form of rickety lateral curvature which occasionally occurs in young children, the most important element is an unequal growth of the bodies of the vertebræ on the two sides. This occurs as soon as the slightest amount of lateral curvature is maintained by faulty positions. The weight of the upper part of the body is transmitted chiefly through those portions of the vertebral bodies which form the concavity of any existing curve. In the areas of maximum pressure the growth of the rickety bone is readily interfered with and thus the curve is constantly exaggerated by deficient bone growth on the concave side as compared with that on the convex side.

**Signs of Lateral Curvature.**—The signs of this affection, when it is well marked, are obvious. In the majority of cases the dorsal curvature is convex to the right side and the lumbar curvature to the left. The amount of the deviation becomes more apparent if the position of the tip of each spinous process is marked on the skin with ink. It must, however, be remembered that, on account of the rotation of the vertebræ, the curve thus produced is much less marked than one which would be formed by a line drawn through the centres of the bodies. This rotation of the vertebræ produces a very characteristic deformity of the chest. Thus the ribs on the right side are thrown backwards and become unusually curved in their posterior parts; and as a necessary result of this the right scapula becomes unduly prominent, so that often the first symptom of lateral curvature which attracts attention is the “growing-out” of the right shoulder. For the same reason the left ribs are sunk and depressed behind, whilst they project in front, throwing the sternum over to the right of the middle line and causing projection forwards of the left breast. The intercostal spaces are widened on the right side, whilst on the left side the ribs are crowded together.

When, as is usual, the lumbar curve is directed to the left, the pelvis

Fig. 426. — Lateral Curvature of Spine.

becomes tilted downwards on the left side; the left loin is prominent and convex, while the right is hollow, and the right iliac crest is more prominent than the left.

Very commonly there is a good deal of neuralgic tenderness about the spine, constituting the ordinary irritable or hysterical spine, and at this early stage there may be anæmia and symptoms of impaired nutrition.

In the more advanced stages, general debility, emaciation, and pallor come on; the mal-nutrition of the body, which was the primary cause of the curvature, being increased by the compression to which the thoracic and abdominal organs are subjected.

During the early period of the case, the spine preserves its flexibility; and whilst the curve is still recent, and the patient young, if the weight of the head and shoulders be taken off, it will at once resume its straight direction. Thus, if the patient be lifted off the ground by raising her up with the hands under the axillæ, or if she be laid down on her face on a flat couch, the back will fall into a straight position, or may readily be made to do so by slight traction. After the affection has existed for some time, or if the patient have passed that age at which consolidation of the bones and ligaments is completed, the distortion will continue permanently, in whatever position she may be placed. This is not only owing to the deformity of the spine, but to the ribs, and the ligamentous and muscular structures generally of the trunk, having become distorted, shortened, and fixed in their abnormal position.

**Treatment.**—The treatment of lateral curvature of the spine should be conducted on rational principles; and, when divested of the mystery with which some interested specialists have surrounded it, becomes simple enough. There are three principles of treatment that require to be carried out in these cases. The first is the improvement of the general health,—unless this be effected, nothing can be done; the second is, to strengthen the muscles of the spine; and the third, to avoid all faulty attitudes of rest by which the curved position of the spine is maintained.

The administration of some of the milder preparations of iron, with a course of aloëtics for the regulation of the uterine function, is of great moment; at the same time, a nourishing diet of animal food should be allowed, and the patient encouraged to take exercise in the open air. By these means the nutrition of the system will be improved, and the tone of the muscles restored. The greatest attention must be paid to the position which the patient assumes when sitting. She must sit quite squarely at the table and should write or draw upon a sloping desk so that the tendency to lean forward is corrected. The chair should have a high back which slopes slightly backwards, and against this the patient's shoulders must rest. Should there be any error in the accommodative power of the eyes, this must be corrected by the use of proper glasses. If the girl rides, she should learn to sit alternately on the off and near sides. Standing still must be avoided, and the patient particularly cautioned against lolling about with the weight of the body resting more on one leg than the other. The patient should sleep on a firm mattress, with the head on a low pillow.

Amongst the most valuable means of strengthening the spinal muscles are douching and massage and the regular performance of suitable exercises. The back should be well douched with cold or tepid salt water every morning and evening, and the muscles methodically rubbed from top to bottom, either

with the naked hand, or with a slightly stimulating embrocation. At the same time, if the patient's strength will permit it, the use of the hand-swing may be allowed. A simple plan consists in hanging a cross-bar from two hooks in the top of a doorway at such a height that the patient can just reach it by raising herself on her toes. Whilst the spine is extended in this way the douching and massage may be practised.

Bernard Roth, who has paid particular attention to the treatment of lateral curvature by the employment of regular muscular exercises, has formulated a series which will be found most valuable. Without describing each exercise in detail, it may be useful to indicate some of the chief ones. Whilst the patient lies flat on the back four slow deep inspirations are taken, with the arms by the side and afterwards extended over the head; rotation and lateral flexion of the head are then slowly repeated four times; circumduction of both shoulders with the elbows extended, and then of each hip separately, is next performed ten or twelve times. The circumduction of the hips is also practised while the patient lies in the prone position. Another exercise consists in the patient lying prone on a flat table with the head and shoulders projecting over the end and slowly flexing and extending the spine. No exercises must be sufficiently prolonged to cause actual fatigue, and after them the patient should rest awhile on a couch or chair. Roth has insisted upon the importance of ascertaining in what position the deformity of the spine is best relieved—as by extending one arm above the head and holding the other at right angles with the trunk—and making the daily assumption of this position for a variable time part of the treatment.

The **recumbent position** in the treatment of lateral curvature of the spine, though a valuable means as an adjunct to other measures, has been greatly abused. In some cases of great weakness the patient must be kept lying during the greater part of the day, but in the majority of cases prolonged rest on the back is harmful by increasing the muscular weakness, and should only be prescribed for resting the patient after walking or the performance of muscular exercises.

**Mechanical contrivances** of all kinds should, as far as possible, be avoided. Great evil may be occasioned and the deformity increased by the unnecessary employment of cumbersome machinery. The heavy apparatus that is often applied to growing girls overpowers and compresses, rather than supports and directs, the imperfectly developed and still yielding skeleton. By the use of complicated machines the muscles of the back become weakened and atrophied from disuse; the pelvis is compressed and contracted; and those very evils are produced by the mechanician which it is the object of the Surgeon to avert or correct.

In some long-standing and severe cases however, in which the deformity

Fig. 627. — Spinal Support for Advanced Lateral Curvature.

has become permanent, the patient may derive great comfort from the use of the apparatus represented in Fig. 627. This takes its basis of support from a strong well-fitting pelvic band to which the weight of the upper part of the body is transmitted by lateral crutches.

Sayre's plaster jacket has been used for lateral curvature, but is now generally condemned, as it prevents movement completely, and thus increases the weakness of the muscles. A poro-plastic jacket, however, which can be removed for washing, rubbing and exercise may with advantage be used in the place of more costly and complicated apparatus.

In cases of posterior excurvation or posterior incurvation of the spine, which we have seen occasionally results from causes similar to those which produce lateral curvature, the treatment must be carried out on the same lines as those above described, and all varieties of mechanical support should as far as possible be avoided.

**Secondary lateral curvature** is met with chiefly in cases of contraction of one side of the chest following empyema, and is a not unfrequent result of any condition which causes inequality in the length of the lower extremities. When the curvature results from the former condition, the spine is curved laterally so that its concavity is directed towards the contracted side of the thorax. The deformity is necessarily irremediable, being due to the falling together of the parietes resulting from imperfect expansion of the lung.

The second variety, which is caused by unequal length of the lower limbs must, if possible, be prevented by the use of a high boot on the foot of the shorter limb. This must be remembered in the treatment of cases in which the shortening results from hip-joint disease or from the operation of excision of the upper end of the femur undertaken for that disease. The convexity of the lumbar curve is directed to the side of the shorter limb and the compensating curve in the dorsal region has the opposite direction.

A certain amount of lateral curvature is seen not uncommonly in cases of angular deformity due to caries of the vertebræ when the destruction of the bodies is greater on one side than the other.

#### DEFORMITIES OF THE NECK AND LIMBS.

Various deformities, such as squint, wry-neck, and club-foot, are due to a disturbance of the normal equilibrium that exists between antagonistic muscles, so that, by the paralysis of one set, or by the spasmodic action of the other, the proper balance of power is lost, and the limb or part deviates from the position that is natural to it, being drawn aside by the more powerful set of muscles. These deformities may be congenital, or they may be acquired.

The primary mischief is, in many cases, seated in the nervous system; in others, but more rarely, in the muscular. The ligaments and bones become only secondarily altered in shape, being shortened or compressed on the side towards which the limb or part inclines or is drawn. Fasciæ also become shortened and tense, and the disused muscles are apt to become wasted and flabby. The contracted muscle after a time may become permanently rigid and shortened.

**CAUSES.**—The causes of these deformities are very various; but they may be referred to the following heads:—

1. **Prolonged Abnormal Position** of a limb, as in an unreduced disloca-

tion or an ankylosed joint, may lead to permanent deformity. It may be taken as a general pathological law that ligaments, fasciæ, and to a less extent muscles, if kept for a sufficient length of time in a continuously relaxed state, become shortened to accommodate themselves to the position in which they have been placed, and thus render permanent the displacement which originally caused the relaxation. The most marked example of this is seen in cases of neglected psoas abscess amongst the poor, in which the patient has been allowed to lie in bed for months before death with the knees constantly flexed. After a time complete extension becomes impossible, and dissection proves that this is due to shortening of those ligaments that are relaxed in flexion. A similar shortening of ligaments or fasciæ may occur after fractures, if the parts be kept for too long a time in one position, more particularly if they be bound and matted together by the pressure of tight bandages. There is no danger however of such a condition being developed in the time ordinarily required for the treatment of a fracture. Some forms of congenital club-foot are believed to be due to a prolonged abnormal position of the limb during intra-uterine life.

2. **Contraction of inflammatory new growths or of tissues which have been infiltrated with inflammatory exudations** is a fruitful cause of deformities. As examples may be mentioned, the contraction of the cicatrices of burns in any part of the body, acquired talipes equinus from contraction following a deep-seated abscess in the calf, and contracted knee or hip after inflammation of the joint.

3. **Derangement of the proper antagonistic action of certain groups of Muscles.**—This may arise from a variety of causes.

(A.) *The Position of the Limb* may give one group of muscles an advantage over their opponents: thus, in disease of the knee, the flexed position gives the flexor muscles an advantage over the extensors, and we consequently find that the head of the tibia becomes after a time displaced to a greater or less degree backwards into the ham, merely by the tonic contraction of the muscles without any weakness or paralysis of their opponents.

(B.) *Paralysis or paresis of one group of muscles*, the contractility of their antagonists continuing normal, is a common cause of deformity, as the relative balance of action is destroyed, and the stronger muscles will pull the part over to their side. The causes of this condition may be in the muscles themselves, in the nerve supplying them, or in the central nervous system.

The muscle itself is seldom the seat of the primary lesion. G. V. Poore has pointed out that a single muscle or group of muscles may be weakened, and their contractility in response to electricity impaired by excessive use without sufficient intervals of rest. This is often accompanied by spasm of the opponent muscles, sometimes tonic, but more often clonic, and thus deformity may result. This is not however a common cause of actual deformity.

The conductivity of a motor nerve is frequently abolished by wound, injury, pressure of a tumour, exposure to cold, or neuritis from other causes. A good example of the effects of lesion of a motor nerve in producing deformity may be seen in the peculiar condition of the hand and forearm, described in Vol. I., p. 593, as resulting from paralysis of the musculo-spiral nerve in certain fractures of the humerus. In paralysis of the facial nerve from cold the face is drawn to the sound side. Internal squint may result from paralysis of the sixth nerve from pressure upon it as it enters the orbit, the external rectus

losing its power and the eye being rotated inwards by the action of its antagonist, the internal rectus.

Disease of the central nervous system, more especially of the spinal cord, is a frequent cause of deformity, which is very common in infancy and early childhood, as a consequence of Infantile Paralysis. This disease is due to inflammation of the anterior grey cornua of the cord. At first there is extensive paralysis, which gradually clears up as the acute stage passes off, often leaving merely a single group of muscles permanently powerless, as for instance, the tibialis anticus, and the extensors of the toes. As the result of this the foot becomes extended by the unopposed muscles of the calf, and one form of acquired club-foot is produced. Little made the important observation that many cases of deformity in infants appear to be due to mischief inflicted on the base of the brain during protracted and instrumental labours.

Another example of deformity from disease of the central nervous system is the club-foot, and occasionally club-hand also, met with in cases of encephalocele or spina bifida.

(c.) *Spasm of a muscle or group of muscles* also may give rise to deformity, the opponent muscles remaining perfect in their contractility, but being overbalanced by the continued contraction of their antagonists.

Spasm may be the result of direct irritation of the central nervous system. This would appear to be the case in some forms of squint. It may also be reflex, resulting from some peripheral irritation. This we commonly see happen in cases of contraction occurring from the cutting of teeth, the irritation of worms in the intestinal canal, in the so-called hysterical contractions from uterine irritation, &c. From all these various causes, contraction and consequent deformity may arise. In some cases deformity will cease after removal of the cause; but in other instances, in which it has been of long duration, the deformity will continue, owing to the muscles having fallen into a kind of rigid atrophy, being shortened and wasted.

4. When deformity has arisen in the lower extremity as a consequence of any of the above conditions, it becomes greatly aggravated by the *weight of the body* acting on the deformed limb. This we see specially marked in old club-feet.

**Treatment.**—The *General Treatment* of deformity consists in removing the cause of the contraction in those cases in which it is dependent on central or peripheral disease or irritation that admits of remedy. Thus, if squinting arise from pressure upon the brain, the eye will resume its straight direction when the congested vessels are relieved, or the effused fluid absorbed; or if a contraction of the hamstring muscles arises from the irritation of worms in the intestinal canal, a purgative dose may cure the affection.

Electricity is perhaps the most valuable agent we possess for the treatment of those deformities that arise from paralysis of one set of muscles allowing those that retain their healthy contractility to draw the parts over to their side. Thus, for instance, if the muscles supplied by the external popliteal nerve, the tibialis anticus, the extensors of the toes, and the peronei—are paralysed, so that the muscles of the calf, the tibialis posticus, and the flexors of the toes draw the foot into the position of Talipes Equinus and Varus, the electricity must be applied to the former group of muscles. The continuous current will be found the most efficient, faradization being of but little use if

degenerative changes have commenced in the paralysed muscles. In the case just described the sponge connected with the positive pole should be tied over the external popliteal nerve behind the head of the fibula, and the negative sponge applied freely over the paralysed muscles till the skin becomes slightly reddened.\*

Friction properly applied forms a useful adjunct to electricity, and great care must be taken to keep the limb warm by proper clothing, without which the other treatment will be of little avail.

In many cases, the contraction may be slowly but very effectually overcome by the use of suitable apparatus, a constant elastic or tensive action being kept up by means of bands of vulcanized india-rubber or steel springs. The details of these various appliances, though belonging to the department of the instrument-maker, cannot be too carefully studied by the Surgeon, who, after all, in order to guide and control their action, must be thoroughly conversant with the mechanical principles involved in their construction. In many of the slighter and less chronic cases, the deformity may be remedied by the employment of these milder means, singly or conjoined; but in those which are congenital or more permanent, the *Division of the Tendons* at fault is the best mode of restoring the natural condition of the part. The *orthopaedic* department of surgery owes, in a great measure, its existence to Delpech and Stromeyer, and its perfection to Little, Tamplin, Adams, and others.

**Tenotomy.**—By tenotomy, as at present practised, is meant the subcutaneous division of a contracted tendon by means of a narrow-bladed knife (Figs. 628, 629, 630) introduced obliquely through a puncture by its side. In doing this, it should be borne in mind that the normal anatomical relations of parts are often a good deal disturbed in cases of deformity: and thus tendons may be approximated to arteries and nerves, from which, in the healthy condition of the limb, they are widely separated.

In the operation of subcutaneous tenotomy the knife may be used in one of two ways. In the majority of cases the tendon may be most conveniently divided by introducing the blade beneath it sideways, and then turning the edge against it, and scratching through it by a kind of fine sawing movement, whilst it is made tense by an assistant. The knife should, if possible, be used as a lever, the back being firmly pressed against some resisting point. If the blade be pressed directly forwards, there is some danger that it may suddenly cut through the skin as the tendon gives way. The second way is to pass the tenotome superficially to the tendon between it and the skin, and then to turn the edge against it whilst it is made tight by an assistant. By this plan the danger of wounding the skin is avoided. Only a drop or two of blood is lost in the operation; and, as the divided tendon retracts with a kind of snap, a

Figs. 628, 629, 630.—Tenotomes.

\* For details of the treatment of paralysed muscles by electricity, I must refer the reader to special works on the subject, especially the selection by G. V. Poore from the Works of Duchenne, published by the New Sydenham Society in 1884.

gap will be left between the two ends, from half an inch to an inch in width, according to the previous amount of tension in the part. If the muscles have been contracted for some years, it will commonly be found that the fasciæ in the neighbourhood of the tendon have become rigid and unyielding, forming cords or bands stretching across from the side of the gap. If these be very tense, they may be divided in the same way: but in many instances it will be found, after a short time, that they will yield by stretching, and consequently will not require division. After the section has been made, the small puncture should be closed with a pad of lint and a strip of plaster, or some cotton-wool and collodion. The admission of air should be carefully guarded against, lest it carry with it impurities which might give rise to inflammation and suppuration. For the same reason the knife should be cleaned in carbolic lotion and the skin washed with the same before the operation. Even without any antiseptic precautions, however, it is very rarely that suppuration follows subcutaneous tenotomy, if performed with ordinary care.

After tenotomy the part should be brought at once into the best possible position and fixed by the use of a suitable splint or other appliance. As a rule the position can subsequently be improved by reapplying the apparatus at intervals and by the use of rubbing and massage; in this way other tense structures, such as ligaments and fasciæ are gradually stretched. It was at one time the practice not to begin extension until three or four days after the operation, the view being held that it was advisable to allow the divided ends of the tendon to unite by soft plastic material before any attempt was made to remedy the deformity. Immediate extension, as suggested by Sayre, is now, however, universally adopted.

The mode of **Repair of Divided Tendons** has given rise to some controversy, there being two theories with regard to the process. According to one, the granulation tissue between the divided and retracted ends gradually undergoes a process of contraction, analogous to that which takes place in the cicatrix of a burn, so as to cause approximation of the cut ends of the tendon at the expense of the muscle, which becomes partially lengthened, until at last merely a transverse linear cicatrix is left at the line of section. Adams has, however, conclusively shown that this theory is erroneous, and that repair is effected by the formation of vascular granulation tissue between the cut ends, chiefly from the sheath and soft parts around; that this undergoes gradual development into fibrous tissue; and that the tendon is actually lengthened and remains permanently so, though perhaps not to the full extent of the gap at first existing between its ends. The new material eventually resembles the normal structure of tendon so closely that the microscope fails to detect any appreciable difference, and it can be distinguished only by its more translucent appearance from the old tendon.

In cases of congenital malformation, the question frequently arises whether tenotomy should be performed in early infancy, or delayed to a more advanced age. As a general rule I think that, if operation will certainly be necessary, it should not be delayed: it is not more difficult at an early period of life than at any other; no danger attends it, and when performed during infancy, there is a far less chance of the deformity being permanent, than if the operation be delayed for some years. But it must be remembered that many slight deformities and contractions in infants may be removed without operation, by attention to proper mechanical and hygienic means. The

Surgeon should not, therefore, be too ready to operate in slight cases at tender ages.

#### DEFORMITIES AFFECTING THE FACE AND NECK.

**Wry-neck, Torticollis or Caput Obstipum**, is characterized by a faulty position of the head, which usually takes the form of lateral flexion of the neck, so that the head is approximated to one or other shoulder. The cases which are included under the general name of "wry-neck," may result from very different causes of which by far the most important are various conditions of temporary contraction, permanent retraction, or spasmodic action of one or more of the muscles of the neck, especially the sterno-mastoids. Torticollis may, however, result from the traction of the cicatrices of burns of the side of the neck, and also from disease of the bones or joints of the cervical spine. It is often a matter of some difficulty to distinguish the deformity resulting from spinal disease from the ordinary forms of muscular torticollis.

A simple transient form of torticollis is often met with as the "stiff neck" following exposure to cold. This is often spoken of as "rheumatic," but it must be clearly distinguished from certain intractable forms which are sometimes associated with or follow other manifestations of rheumatism. In these cases the sterno-mastoid may be affected, but often the posterior muscles of the neck, especially the trapezius and the splenius capitis, appear to be chiefly at fault. This condition is very liable to become chronic and lead to permanent retraction of the affected muscles. Wry-neck occasionally comes on in childhood after measles or scarlet fever, usually as a consequence of inflamed cervical glands, and is then due to the position instinctively assumed by the head in order to relax the muscular tension on the inflamed side of the neck.

The chronic forms of muscular torticollis are due in most cases to retraction of one sterno-mastoid. This condition is generally met with in childhood, but in rare cases appears to be congenital and may possibly then be due to malposition in the uterus. It has long been thought probable that some cases of torticollis occurring in childhood owe their origin to some damage of one sterno-mastoid muscle during birth. It is now generally recognized that the hard swelling which is occasionally present in this muscle in infants is the result of partial rupture of the fibres, due usually to traction on the after-coming head in breech presentations (Chap. LIV., p. 613). The relation between this hæmatoma of the sterno-mastoid and the subsequent development of torticollis has been carefully investigated by numerous observers, and the fact has been established by Volkmann, Clutton, Owen, D'Arcy Power, and others, that in a certain proportion of cases gradual retraction occurs in the damaged muscle with the production of varying degrees of torticollis. Power finds that of 106 cases of hæmatoma of the sterno-mastoid which he was able to collect, well-marked wry-neck followed in at least 21 cases. In this variety of the deformity the muscle of the right side is the more usually affected. Permanent retraction of the sterno-mastoid or other muscles is an occasional sequel of the acute rheumatic contractions above mentioned. Paralysis of one sterno-mastoid is a very rare cause of wry-neck; the deformity is produced by the unopposed contraction of the muscle of the opposite side which may after a time become permanently retracted.

Spasmodic torticollis is an unusual form due to clonic or tonic contractions

of the sterno-mastoid or other muscles of the neck, such as the trapezius or splenius. The spasm may be completely intermittent, each attack coming on suddenly with great pain and the affected muscles relaxing again after a variable time. In cases of long standing the spasm is liable to become tonic, and finally some permanent retraction of the muscle results. In the earlier stages the spasm may be overcome by gentle traction and disappears entirely when the patient is anaesthetized. In cases in which the sterno-mastoid or trapezius is affected, it is probable that the spinal accessory nerve is at fault or that the spasm may result from some central lesion. An interesting case probably of this nature has been recorded by Poore. The muscles chiefly affected were the left sterno-mastoid and the right splenius capitis, which are associated in turning the head to the right. The sternal head of the sterno-mastoid had been divided with only temporary relief. The patient had had syphilis. There was a small scar on the scalp close to the middle line and near the left coronal suture, a position which agrees with Ferrier's centre for rotation of the head to the opposite side. Complete relief followed a course of mercury; otherwise it had been decided to trephine over the position of the scar, on the supposition that some meningeal thickening beneath this might be the cause of the spasm. When the spasm affects the deep posterior muscles of the neck it is the posterior cervical nerves which are probably at fault.

Hysterical torticollis is occasionally met with in young females who exhibit other evidences of functional disorder. In these cases the head may assume any position, but often it is flexed laterally and the shoulder raised. The disappearance of the deformity under an anaesthetic and the general features of the case will usually serve to indicate its nature.

The **Symptoms** vary considerably in different cases. When the deformity arises from retraction of one sterno-mastoid, a triple displacement of the head results: it is drawn downwards towards the shoulder of the affected side, whilst the face is turned to the opposite side and slightly upwards.

The affected sterno-cleido-mastoid will be found hard, defined, and shortened; sometimes both divisions of the muscle are equally tense, standing out in strong relief, so as to look almost like two distinct muscles. In other cases, one division, and then more usually the sternal, is chiefly affected. After a time the cervical vertebrae participate in and maintain the displacement, becoming rotated on their axes and curved. Eventually the whole spinal column shares in the displacement, and lateral curvature sets in. The deeper muscles also become shortened, and the anterior margin and clavicular attachment of the trapezius will often be found tense and preternaturally defined.

In well-marked cases of torticollis the features lose their symmetry, and the lines of the eye-brows, eyes, and mouth are lower on the side towards which the head is inclined. In advanced cases the whole side of the face and even of the head may be distinctly flattened. This asymmetry of the face is the result of imperfect development when the torticollis occurs in infants; but it has been observed to occur when the torticollis arises in adults, and under these circumstances it has been suggested that it is due to impaired nutrition from interference with the circulation through the carotid on the contracted side.

In spasmodic torticollis the position which the head assumes during the attacks of spasm will depend upon which muscles are affected. Spasm of one

sterno-mastoid will throw the head into the position above described ; if both muscles are affected the head is thrown forwards. In spasm of the posterior muscles varying degrees of extension and rotation are met with. Thus one trapezius will draw the head backwards with a slight inclination of the face to the opposite side ; both trapezii acting together will simply extend the head. The splenius capitis inclines the head laterally and rotates the face to the same side, and acting with the sterno-mastoid of the opposite side will serve to increase the rotation produced by the latter muscle. It has already been mentioned that in long-standing cases of spasmodic wry-neck the deformity may be rendered permanent by retraction of the affected muscles. Purely spasmodic torticollis can be distinguished from that due to permanent shortening of the muscles by the fact that it is often paroxysmal, that the deformity can be overcome by traction, and that it disappears during sleep and anæsthesia.

The greatest care must be taken not to confound muscular torticollis with disease of the cervical spine. It must be remembered that spasmodic muscular contractions in the neck may result from irritation of the nerve roots at the intervertebral foramina. In the case of torticollis due to retraction of one sterno-mastoid, the freedom of the movements other than those limited by the shortened muscle will serve to distinguish it from the deformity following spinal disease, whilst from early cases it differs in the absence of pain and complete freedom from swelling or thickening about the vertebræ.

The **Treatment** of the acute forms of torticollis such as that which follows exposure to cold consists in rest of the part and the application of warmth, followed by rubbing with stimulating liniments. If the deformity be secondary to inflamed cervical glands these must receive appropriate treatment.

In a well-marked case of torticollis, arising from permanent shortening of one of the sterno-mastoids, which is the common form of the affection, the treatment may best be conducted by dividing the inferior attachment of the muscle, and thus allowing the head to regain its proper position. The *subcutaneous division* of the muscle is a somewhat delicate operation, on account of the important structures that lie immediately behind it. By dividing it, however, from behind forwards, close to the sternum and along the clavicle, there can, if ordinary care be employed, be little risk of doing any damage, as these bones carry the lower attachment of the muscle forwards, and separate it from subjacent parts. The sternal attachment of the muscle, which is usually very tense and prominent, may be divided by making a puncture on the inner side of the tendon, pushing a narrow director behind the muscle, drawing the latter forwards, and then passing an ordinary tenotome behind the tendon, with its flat side towards it, just in front of the upper margin of the sternum, and cutting forwards, whilst the muscle is put well upon the stretch. In dividing the clavicular origin, a puncture should be made with a scalpel upon and down to the clavicle in the cellular space which lies between the two attachments of the muscle, and then by pushing a long, blunt-pointed, narrow-bladed tenotome beneath the insertion of the muscle, this is divided in a direction forwards. In this situation also the director may be used, unless the parts are very tense. Care must be taken of the external jugular vein at the outer edge of the muscle. Should this vessel run inconveniently close to the edge, the safer plan is to begin the operation from the outer side, making

the first puncture here. After division of the tendon, the deep fascia of the neck will sometimes be found stretching across in firm and tense bands; these, however, had better not be interfered with, as they will yield in time, and great risk of injuring the subclavian and carotid vessels would attend any attempt at their division. Nor should the edge of the knife ever be turned inwards. Care must be taken to divide the muscle completely, but not to carry the incision too freely or deeply. I have heard of more than one case in which, from want of due precaution, abundant hæmorrhage occurred, and of three in which a fatal result followed the operation.

The dangers of the subcutaneous division of the sterno-mastoid can be avoided, and the operation performed more thoroughly, by means of the *open method*. This consists in making a short transverse incision over the muscle about one finger's breadth above the clavicle. The muscle is then carefully divided as completely as may be necessary with forceps and scalpel.

If the open method be adopted with careful antiseptic precautions, it is certainly in every way superior to the subcutaneous mode of division.

After the operation the head must be maintained in the best possible position by the use of a suitable apparatus. The complicated instruments which consist of a spinal support with an arrangement of pads, by which pressure can be brought to bear upon the head in different directions, have been discarded almost entirely in favour of simpler means. One of the best methods consists in applying a plaster jacket in the same way as for spinal disease, and moulding a poroplastic cap to the head, or fixing a stout strip of plaster circularly around it. The head is then kept in position by the use of one or more india-rubber cords, which are attached by one end to the cap or strapping, and by the other to a hook in the plaster jacket. Several hooks should be fixed to the jacket so that the direction of the traction on the head may be altered at will. As a rule one band should be so arranged that it exerts its traction in the line of the sterno-mastoid muscle opposite to that which has been divided. Manipulation and massage will much assist in rectifying the position.

In the treatment of *spasmodic torticollis* any condition which might act upon the muscle reflexly must be sought for and relieved. A thorough trial must be given to the constant current and massage, whilst it is of much importance to attend to the condition of the general health. When the sterno-mastoid is affected, the spasm has been relieved for a while by dividing the muscle, but, if any operative interference be necessary, the choice must lie between stretching and excision of the spinal accessory nerve. Of these methods the latter is to be preferred, and neurectomy should certainly be performed if other measures have failed to relieve the spasm.

The nerve is best reached by an incision along the anterior border of the sterno-mastoid, beginning at the apex of the mastoid process, and extending downwards for three inches. The edge of the muscle is freely exposed and turned outwards until the nerve is seen entering its deep surface. This it does at a point about two inches below the mastoid, or opposite the angle of the jaw. If any difficulty arise in recognising the nerve, Ballance recommends that the lower border of the digastric be defined in the upper part of the wound; the spinal accessory escapes from beneath this muscle just below the transverse process of the atlas. An inch or more of the nerve should be excised, and the proximal end thoroughly stretched, or completely avulsed.

Campbell de Morgan, who first excised a portion of the spinal accessory in 1862, exposed the nerve at the posterior border of the sterno-mastoid. This method is not suited for cases in which the sterno-mastoid is affected. The immediate result of the operation is to paralyze, more or less completely, the sterno-mastoid and trapezius and relieve the spasm. In a considerable number of cases the relief has been permanent, although the paralysis has improved. In other cases the spasm has returned after a variable interval, and sometimes has spread to other muscles. Petit in 1891 collected 26 cases of neurectomy of the spinal accessory for spasmodic torticollis: in 13 the result was successful; 7 were improved, 2 were slightly better, 3 had temporary relief, and 1 died of erysipelas. Southam has performed the operation in 10 cases; four of these were known to be completely relieved after periods varying from two to eight years.

In a case of severe spasm affecting the posterior muscles of the neck in which no relief followed other measures, Keen excised parts of the posterior primary divisions of the first, second, and third cervical nerves. The operation afforded marked, but not complete, relief. Similar treatment has been adopted by Noble Smith and others, but the cases in which such severe measures are justified are necessarily extremely rare.

In those cases in which the wry-neck appears to be dependent rather on paralysis of one sterno-mastoid than on spasm of the other, electricity will be found most useful.

#### DEFORMITIES OF THE ARM AND HAND.

**Contraction of the Arm** is not of very common occurrence, except as the result of burns. I have, however, met with four distinct forms of contraction of the forearm.

1. There may be ankylosis of the elbow-joint, the forearm being bent at a right angle with the arm, the result of disease in or around the articulation. If the ankylosis be fibrous, and the muscles strong and firm, a very useful limb may be restored by breaking down adhesions, under chloroform; by forcible flexion and extension, followed by the use of passive motion, friction, and douches. Should the muscles be very flaccid and wasted, forcible extension may leave a permanently weakened limb, over which the patient has lost the power of flexion. In such cases I have found gradual extension, made by means of an angular splint acted upon by a racket-apparatus, the safest means of restoring the utility of the arm. If the ankylosis be osseous, the bones should be resected, a wedge-shaped piece being sawn out, and a false joint allowed to form.

2. The biceps may, by its contraction, occasion a permanent flexion of the arm. This contraction of the biceps may be hysterical, rheumatic, or syphilitic. The syphilitic form may be due to gummatous infiltration of the muscle. When it is hysterical, occurring in young women, it requires the ordinary constitutional treatment of hysteria; should this fail in removing it, extension may be made, under chloroform, and the arm kept in a straight position for a time. When it is syphilitic the ordinary treatment of syphilis may produce a cure. When of organic character, and permanent, section of the tendon and its aponeurosis may be practised, due care being taken of the brachial artery and median nerve. This operation is most safely done by

introducing the tenotome to the inner side of the tendon, slipping it under, and cutting upwards and outwards; the artery being guarded and pushed to the inner side by the pressure of the left forefinger.

3. The forearm may be forcibly pronated and flexed as the result of chronic inflammation of the radio-humeral articulation. Here forcible supination and extension, under chloroform, is the best remedy.

4. The forearm may be bent on the arm in consequence of the contraction of the cicatrix of a burn along the inside of the limb. In this case the plastic operation described in Vol. I., p. 401, must be practised.

**Ankylosis of the Arm in the Straight Position** is a condition of very

Fig. 631.—Contraction of Supinators of Forearm and Extensors of the Hand.

serious inconvenience, the limb being almost useless for all ordinary purposes of life. In cases of this kind, the treatment to be adopted must depend upon whether the ankylosis be fibrous or osseous. If it be fibrous, however firm, the forearm may always readily be brought into a rectangular position by flexion under chloroform, and the mobility of the joint may then be improved or restored by passive motion, friction, and douches. If it be osseous, a wedge of bone must be removed, and the case treated as an ordinary instance of excision of the elbow, with a view of establishing a false joint.

**Acquired Contraction of the Muscles of the Forearm implicating**

Fig. 632.—Contraction of Flexors and Pronators of the Hand.

**the Hand** is occasionally met with in adults. I have seen it in two opposite conditions: that of forcible extension (Fig. 631), and that of forcible flexion and pronation (Fig. 632). In both instances it appeared to have been the result of excessive use of certain muscles; in the first case in wringing out clothes, in the other in cutting with very heavy shears. In the case of flexion and pronation, it was interesting to observe that, when the fingers were extended, the wrist became flexed, and when the wrist was extended the fingers became bent in. In these cases change of occupation, friction, and galvanism, with the use of a straight splint, were advantageously resorted to, a cure being eventually effected.

**Paralysis of the Extensors and Supinators**, owing to the injury of the musculo-spiral nerve consequent on fracture of the humerus, has been described in Vol. I., p. 593.

**Club-hand.**—A deformity resembling club-foot is occasionally, though rarely, met with in the hand. The contraction may occur in two directions : either in the sense of preternatural flexion, or in that of abnormal extension of the member. It has been described by Cruveilhier, Voillermier, and Smith of Dublin. In most of the cases that have been met with, there was a certain amount of deformity of the lower end of the radius, with congenital dislocation of the wrist ; and in Smith's case there was an accessory semilunar bone in the carpus. In other cases it has been caused by congenital absence of the radius. Little, if anything, can be done by surgery for the relief of this deformity.

**Arthritis Deformans or Rheumatoid Arthritis** of the hand is a common affection. In this condition, the fingers which are thickened and stiffened are partially bent towards the palm, and at the same time turned towards the ulnar side. The articulations are swollen, and in the earlier stages painful. The disease rarely occurs before middle age. It is more common in elderly people, and especially those of the labouring class, whose hands have been much exposed to the weather, with the fingers bent as in holding reins or agricultural implements. The deformity is permanent and incurable.

**Dupuytren's Contraction of the Fingers.**—One or more fingers may be bent in consequence of injury of the flexor tendons ; the skin and fascial structures of the palm remaining sound with the exception of some cicatricial tissue. Such a contraction is incurable, as a portion of the tendon has probably sloughed away. In the true digital contraction, commonly called *Dupuytren's contraction*—its pathology having been pointed out by that great Surgeon in 1832—the tendons and their sheaths are unaffected, the deformity being due to changes taking place in the fascial structures outside them. Most commonly this commences in the little finger, and thence gradually extends to the ring and middle fingers, which become so forcibly and firmly flexed, that their extension is not practicable. The thumb and index finger are much less commonly affected. This deformity is very rare in females, and is most commonly met with in males after forty. It has very generally been supposed that the condition results from frequent and continued pressure on the palm of the hand, as in leaning on a round-ended stick in walking, or in those trades in which an instrument is pressed into the hollow of the hand. This, however, seems doubtful ; it certainly often occurs without any apparent exciting cause. In some cases I have found it associated with a rheumatic or gouty diathesis, and Lockwood has demonstrated the presence of uric acid crystals in the thickened fascia removed by operation. On examining the contracted fingers, projecting ridges will be felt extending from the palm to their anterior aspects ; and on endeavouring to straighten them, these ridges will be found to become stretched, and the palmar fascia to be rendered tense. The skin covering these fascial ridges is at first free, but after a time becomes adherent to them. So firmly are the fingers contracted, that by no effort can they be extended.

**Pathology.**—Dupuytren found on dissecting a hand which was the seat of this disease, that after the removal of the skin, which was loose and flaccid,

the contraction continued as before, and this, therefore, could not be its seat : that the palmar fascia, which was exposed, was tense and shortened, whilst from the lower aspect some cord-like prolongations passed up by the side of the fingers ; and that, when these were divided, the contraction was immediately removed, the tendons, the bones, and the joints being perfectly sound. He considered these fibrous cords to be digital prolongations of the palmar fascia, and consequently looked upon this membrane as the seat of the disease. Goyrand, who has carefully dissected hands affected in this way, states that these fibrous cords, which he looks upon as the seat of the affection, are not prolongations of the palmar fascia, but are fibrous structures that extend from its superficial aspect to the sheaths of the flexor tendons, into which they are inserted opposite the second phalanx ; being formed by hypertrophy of bands of subcutaneous connective tissue which naturally exist in this situation. W. Anderson, who also has investigated the pathology of these cases, describes the contraction as due to "an inflammatory hyperplasia commencing in the subcutaneous tissue of the palm, involving the skin and fascia secondarily, and replacing the adipose connective tissue which normally serves as an elastic cushion for the palmar surface of the hand and fingers." The fact, therefore, remains certain that the flexor tendons have nothing to do with this special form of finger contraction, but that it is due entirely to fibrous cords from the digital divisions of the palmar fascia : and, as Adams has pointed out, the insertion of these digital prolongations of the fascia into the periosteum of the second phalanx readily explains the drawing down of that bone.

The **Diagnosis** of cases of digital contraction, so far as the deformity is concerned, is obvious, and requires no comment ; so far as the cause is concerned, it is not so easy. Is it tendinous or fascial ? When *tendinous*, the contracted tendon can be followed up to and above the wrist as a tense cord, and by flexing the wrist the contracted finger can be partly or completely straightened. When *fascial*, the tendon cannot be clearly defined, but the palmar structures are dense, thickened, and incorporated together, forming distinct ridges and sulci ; flexion of the wrist does not allow the contracted finger to be straightened.

This true digital contraction must not be confounded with the "arthritis deformans" which often distorts the weather-beaten hands of labouring men and sailors. In these cases all the fingers are bent inwards, and more or less twisted to the ulnar side, so that the hand presents a claw-like appearance, the mischief evidently affecting the joints.

**Treatment.**—The treatment of digital contractions is purely mechanical and operative. The progress of the disease may be retarded, and some benefit obtained by the use of finger-splints applied to the dorsal aspect, and provided with elastic tractors. The kind of operation must be determined by the pathological cause of the disease. If the case be one of contraction of the flexor muscle and tendon, tenotomy may be performed, but in Dupuytren's contraction the tendon and its sheath must not be touched, but the contracted structures outside them must be cut across.

Adams, recognizing the true pathology of this affection (Fig. 633), has devised a successful means of remedying it by subcutaneous operation, which should as far as possible be employed instead of an open incision. The plan consists in making multiple subcutaneous divisions of the fascia and its digital prolongations. For this purpose he uses the smallest possible tenotome—little

larger than a cataract-needle; with this instrument about four subcutaneous incisions are made to each finger, not more than one or two fingers being operated on at a time. The first puncture is made in the palm just above the transverse flexion-crease at a point where the skin is least adherent. By the second puncture, the same cord should be divided between the flexion-crease and the web of the fingers. The third and fourth punctures should be made so as to divide the digital prolongations of the fascia. Immediate extension is then made, and the fingers kept straight on a padded metal splint.

In performing this operation the Surgeon must be careful not to carry his incisions or punctures too deeply into the palm, lest the superficial palmar arch or one of its branches be divided. The guide to the commencement of the digital prolongations from the palmar fascia is the *transverse flexion-fold* in the palm. This—as Adams has pointed out—corresponds exactly with the line of the metacarpophalangeal articulations, and is of course well in advance of the superficial palmar arch. By keeping the highest incisions near to this line, no danger to this artery need be feared. Should it be found to be impossible to straighten the fingers with such limited incisions, or should the skin be firmly adherent to the subjacent fibrous band, it has been recommended to make a crucial incision

Fig. 633.—Dupuytren's Contraction (after Adams).

through the skin, to turn the flap back, divide or dissect off the fascial bands from the sheaths of the tendons, and straighten the fingers. As the flexor tendons are not primarily affected, they must not be divided. After the operation, the hand should be placed on a digitated splint and the fingers kept extended. This mode of treatment can only be attempted as a last resource in a useless hand, as the prospect of success is not great.

**Contraction of the finger backwards** is of very rare occurrence. I have seen only one such case, in a lady in whom the little finger of one hand had a crescentic curve backwards; the ring-finger was also slightly affected. This condition, which was permanent for many years, obstinately resisting all treatment, mechanical and constitutional, appeared to be due to chronic neuritis of the cords of the brachial plexus, consequent on a fall on the back of the head and neck.

The name **Hammer Finger** has appropriately been given to a condition occasionally met with in the hand, similar to and sometimes associated with the deformity known as "hammer-toe." The condition usually occurs in early life, and is characterized by flexion of the interphalangeal joints of the finger with usually slight over-extension of the metacarpophalangeal joint. It is generally met with in girls, and usually affects the little finger. W. Adams has pointed out that in the early stages passive extension of the finger is possible, but that this gradually becomes impossible on account of the contraction of the skin and fascia in front of the joints. Anderson found the anterior part of the lateral ligaments tense, and believes this to be the cause of the deformity.

If the finger can be extended the *treatment* should consist in applying a

small straight splint. If, however, the flexion is permanent, Adams recommends that the tense bands of fascia in front of the flexed joints should be divided transversely with a fine fascia knife.

**Congenital Deformities of the Fingers and Hand** are frequently met with and assume very various forms, only the chief of which can be briefly alluded to here.

1. **Congenital Hypertrophy of the Fingers** or **Macroactylism** is a rare condition in which one or more digits grow to a size altogether out of proportion to the rest of the hand, though still maintaining more or less accurately their normal form. Two or three fingers are commonly affected. Attempts have been made to reduce and arrest the growth by pressure but without success. If the large digits are useless, they may be amputated.

2. **Supernumerary Digits** or **Polydactylism** form the most common deformity of the hand. The supernumerary digit is always either at the radial or the ulnar side of the hand, and in three-fifths of the cases it is in the

Fig. 624. - Supernumerary Thumb.

Fig. 625. - Apparent Fusion of Hands.

latter situation. The degree of development of the digit varies greatly. It may be so perfect that it appears to be simply a continuation of the natural series, there being six complete digits instead of five; and Morand describes a hand having a thumb and six well-formed though somewhat shortened fingers. More commonly the supernumerary digit is far from perfect. The presence of a metacarpal bone is rare, but three well-formed phalanges are not uncommonly found attached by a lateral articulation to the inner side of the head of the fifth metacarpal bone. In the least perfect form the finger is represented by a small fleshy lump commonly containing a small central mass of cartilage, and always provided with a rudimentary nail. It is attached to the base of the first phalanx of the little finger by a narrow pedicle. Various intermediate forms are also met with. A supernumerary thumb may be distinctly separate, containing usually two small deformed phalanges, or it may be more or less completely fused with the normal digit, forming a wide mass with a double nail at the end. In other cases the thumb is merely bifid, only the last phalanx being double. All these varieties of deformity of the fingers are more or less hereditary. They may in most cases very easily be removed by an operation, which is simple and perfectly safe, the supernumerary

finger being disarticulated at its base. It is better to do this at as early an age as possible ; no good can possibly come of delay.

In some rare cases, as in that from which the annexed drawing (Fig. 635) was taken, two hands may appear to be fused into one. In these no operation is possible.

3. **Congenital Want of Development of the Fingers or Microdactylism** is a less common deformity. In the extreme forms of this all the fingers may be wanting except the thumb and little finger, which may be approximated to each other like the claws of a crab, the hand being deeply cleft in the situation of the missing fingers.

5. **Partial Congenital Amputation or Dactylolysis** is another rare deformity. The accompanying drawings (Figs. 636 and 637) are representations of a remarkable deformity of the hands in a child that was under my care some years ago. The fingers appear to have suffered in some instances complete, in others partial, amputation *in utero*. They are marked by deep transverse sulci ; others are shortened, and terminate in

Fig. 636.—Left Hand.

Fig. 637.—Right Hand.

Arrest of Development of Fingers.

rounded nodules, with a narrow pedicle connecting them with the proximal phalanx.

**Webbing of the Fingers or Syndactylism** is occasionally met with. In this condition a cutaneous septum unites contiguous fingers. Sometimes the malformation is confined to one digital interspace, and then it is usually that between the index and middle fingers. In other cases it occupies two or all three interspaces. The web is a tolerably thick septum of skin, narrow at the base, broader above. It may extend the whole length of the fingers, or only for a portion. The web does not interfere with the movements of the fingers in flexion or extension.

This deformity is not easily remedied by operation. It would seem extremely simple to divide the web and to keep the fingers apart while the raw surfaces are healing, but experience has shown that this treatment leaves the patient little better than before the operation, as gradual union of the raw surfaces advances from the angle in spite of all that can be done to prevent it. To overcome this difficulty it has been suggested to make a puncture through the web at the base of the space between the fingers, and to pass through this a piece of glass rod or metal, which may be worn until the wound thus made is completely covered by epithelium. When this healing is complete, the web

may be slit up without risk of re-union proceeding from the angle between the fingers.

When the septum is sufficiently thick, the following operation, invented by Didot of Liège, may advantageously be practised. Supposing the index and middle fingers to be webbed, the following would be the procedure to be adopted, which is of course equally applicable to any of the other fingers : 1. The Surgeon makes an incision along the median line of the palmar aspect of the index finger, extending the whole length of the web. 2. Two small transverse incisions are next made at the upper and lower ends of this longitudinal incision, extending from it to the ends of the web. 3. The rectangular flap thus defined is dissected back as thick as possible, so that its back corresponds to the mid-line of the web. 4. A corresponding longitudinal incision is now made along the dorsal surface of the middle finger, but comes rather further down on the hand. The two transverse incisions at its upper and lower ends are next made ; the flap thus defined is dissected back, and when the knife reaches the mid-line of the web the two fingers will be found to be separated. 5. The next and last step of the operation is to wrap each flap

Fig. 638.—Diagram of Flaps, Didot's Operation for Webbed Finger.

Fig. 639.—a. The lines of the two incisions uniting, so as to divide the Web and leave a Flap on each side. b. The Flaps detached from the opposite Fingers to those to which they are adherent. c. The Flaps applied to the Fingers, and covering in the raw and exposed surfaces.

round the raw surface of the finger to which it continues to be attached, and to fix it in position by a sufficient number of horsehair or fine catgut stitches. Thus the raw surface on the index finger will be covered by the flap taken from the dorsum of the middle and *vice versa*, as is seen in the accompanying diagram (Fig. 638).

In the accompanying cut (Fig. 639), transverse sections of the fingers are shown. The operation should not be undertaken at too early an age, as the small size of the parts makes it difficult to do it efficiently. It is doubtful also if the result in after-life is always satisfactory. I have known of a case in which the scars in the site of the divided webs seemed, by contraction and want of growth, to have led to deformity of the fingers even more crippling than the original webbing, and ultimately necessitating partial amputation of one finger which was hopelessly distorted and flexed into the palm. If two fingers only are webbed, they may be left until the hand is fully grown before operation.

If the uniting web is thin the above operation is impracticable, and the method devised by Zeller will be found useful. This consists in raising a

small triangular flap from the dorsum of the web, leaving its base at the level of the natural cleft and its apex opposite the first interphalangeal joint. The web is then divided up to the normal level and the flap turned forwards between the fingers and adjusted with fine sutures. Skin grafting is sometimes useful in these cases.

#### DEFORMITIES OF THE LOWER LIMB.

**Ankylosis of the Hip** has been already described (p. 439), and **Con-genital Dislocation** (Vol. I., p. 704).

#### DEFORMITIES OF THE LEG AND FOOT.

**Genu Valgum.**—The deformity termed **Genu Valgum**, or **Knock-knee**, usually affects both extremities, though it is generally more marked in one than in the other. In it the knee forms the apex of a triangle, the base of which is represented by a line drawn from the trochanter to the outer ankle. Knock-knee arises at two periods of life : first, during early childhood, when it is usually the result of rickets, and is most frequently conjoined with some curvature of the bones of the leg ; and secondly, about puberty, when it is due to relaxation of the ligaments, and is frequently the result of carrying heavy weights. At this period it is often conjoined with weak ankles and flat-foot. In many cases the flat and everted foot is probably the primary affection. Bock states that out of 221 cases which he examined, 17 originated about the period of the first dentition, and 200 between that age and the 15th or 18th year. Some occupations are said to predispose to it, smiths being especially liable to the deformity. In whatever way knock-knee arises there is relaxation or stretching of the internal lateral ligament ; the biceps, the external lateral ligament, and often the vastus externus are tense. The patella is thrown outwards and in some cases undergoes complete external dislocation (see Vol. I., p. 705).

**Mode of Production.**—In the rickety forms of genu valgum the femur is chiefly, and often exclusively, at fault. In some cases the deformity is the result of an abnormal bending of the shaft of the femur, which presents at its lower end a curvature, the convexity of which is directed inwards. As the result of this the internal condyle is necessarily displaced downwards and the leg is thrown outwards to a corresponding extent. Far more frequently, however, the fault lies in the inferior epiphysial line of the femur. On account of the oblique direction of this bone the internal condyle is longer than the external so that the surfaces of the two condyles which rest on the tibia may be in the same horizontal plane. In rickety genu valgum the apparently undue elongation of the internal condyle is not caused by an actual enlargement of the condyle itself, but is due to an unequal growth at the inner and outer parts of the epiphysial line, so that the internal condyle is displaced downwards below a horizontal line drawn through the articular surface of the external condyle. This is probably due, as Humphry suggests, not so much to an excessive growth in the inner part of the epiphysial line as to a defective growth in the outer part. It is a necessary result of the oblique position of the femur that the weight of the body is transmitted more through the outer part of the lower extremity of the bone than through the inner part.

The explanation of cases of rickety genu valgum which therefore seems most satisfactory is that the growth of the rickety bone is especially interfered with in those parts through which the weight is chiefly transmitted, and that thus the increase in length is proportionately greater in the inner half of the epiphysial line than in the outer. Thus the internal condyle is displaced downwards although not itself enlarged. In some instances, the deformity is increased by a curvature of the upper end of the tibia, resulting probably from a deficient growth in its outer part. In those cases in which genu valgum develops in early adult life it is probable that a relaxed condition of the ligaments of the knee-joint is the primary condition. If the subject of a thus weakened joint is compelled to spend the greater part of the day in the standing position, and is, perhaps, engaged in work which involves the carrying of heavy weights, the knee will tend to yield in an inward direction. In cases which arise directly in this way, Little states that a distinct gap, often of considerable width, may be felt between the inner side of the head of the tibia and the femur. Although in this variety

of the deformity the ligaments are primarily affected, the lower end of the femur gradually becomes altered and an apparent enlargement of the internal condyle is produced by a deficient growth in the outer part of the epiphysial line resulting from the undue share of the weight of the body which is thrown upon it.

The important part taken by the relaxation of ligaments in the causation of knock-knee in young adults is well illustrated by the occasional occurrence of the deformity as a sequel of chronic synovitis, and also following excision or arthrectomy of the joint, if the patient be allowed to dispense with support to the joint before the part is thoroughly consolidated. In all forms of genu valgum the deformity disappears when the knee is flexed, because the internal condyle is displaced downwards, but without any corresponding increase in its antero-posterior diameter. In extreme cases of knock-knee the joint is often capable of

Fig. 640.—Apparatus for Knock-knee.

some degree of over-extension, the leg at the same time rotating outwards.

**Treatment.** In young children the treatment of genu valgum should consist in the first place in careful attention to the diet, and the administration of cod-liver oil and tonics. With the object of preventing an increase in the deformity, the child must for a while be kept entirely off its feet. This is best done by applying a light wooden splint, carefully padded, to the outer side of the limb. It should reach from the hip to between two and three inches beyond the foot. The splint is attached to the thigh and leg, by bandages or soft webbing straps, and should be worn constantly except at night. Every morning and evening the limb should be well douched with cold or tepid salt water and thoroughly rubbed, whilst the leg is drawn firmly inwards.

In the case of older children, external wooden splints may still be used, but should not reach beyond the foot, so that the child is able to walk. The

splint is attached to the limb by broad straps above and below the knee, and by another around the ankle, whilst the upper ends of the two splints are joined by a narrow strap passing behind the pelvis, to prevent their tendency to "ride" forwards.

As an alternative, if the greater expense is no drawback, the apparatus represented in Fig. 640, may be used. This consists of a well-padded iron stem reaching along the outer side of the limb from the trochanter to the ankle, and attached above to a pelvic band and below to the boot. Where it corresponds to the knee it should be provided with a hinge, and should have a broad well-padded strap passing over the inner side of the joint, and attached by buckles to the stem, in such a way that by tightening these the knee may be drawn outwards. In all cases of genu valgum the feet should be examined, as much benefit may result from proper treatment directed to the correction of the condition of flat-foot, which is so often present.

Fig. 641.—Genu Valgum; *a*, line of division in MacEwen's operation; *b*, in Ogston's operation.

In a considerable proportion of the cases of knock-knee occurring in rickety children the deformity can be arrested in its early stages by the simple means above described, and often the position of the limb becomes gradually much improved. The cases in which the deformity results from relaxation of the ligaments often require no further treatment than support to the limb, and the adoption of measures directed to the improvement of the general health.

In the more advanced cases, however, operative interference may be required. It is very rarely necessary in young children, and indeed should not as a rule be undertaken in patients under ten. Before that age the deformity can usually be corrected by simpler means, and it is an objection to operative interference

before the rickety process has been recovered from, that relapse is very likely to take place.

The only operative treatment for genu valgum which will be considered here is antiseptic osteotomy. Forcible straightening of the limb, as practised by Delore of Lyons, is too uncertain and dangerous a method to be recommended, whilst no possible good can be expected from subcutaneous division of the biceps tendon for the relief of a deformity due to an alteration in the bone.

**Antiseptic osteotomy** has for its object the restoration of the inner condyle to its normal level. It is impossible here to do more than mention many of the methods that have been employed with this object. In 1875,

Fig. 642. -- MacEwen's osteotome.

Annandale opened the joint and removed the prominent portion of the inner condyle with the saw. This bold operation was completely successful, but since the introduction of simpler methods it has not been repeated. In 1876 Ogston performed, for the first time, the operation of sawing off the inner condyle obliquely by means of an Adams's saw (Fig. 574), introduced through a puncture made in the skin above the inner condyle. In 1878 Macewen modified the operation by removing a wedge-shaped piece of bone in the line of Ogston's saw-cut, but without penetrating so deeply as the articular cartilage, and Reeves at the same time suggested dividing the condyle with a chisel, stopping just short of the cartilage. In 1878 Barwell, regarding the deformity not merely as a lengthening of the inner condyle, but as an obliquity of the whole lower epiphysis, cut through the femur with a chisel a little above the epiphysis from the outer side, and subsequently after some weeks divided the tibia and fibula in the same way about one inch below the articular surfaces. Lastly, Macewen introduced the method of dividing the femur only, immediately above the epiphysis, and, at the present time, this method is almost universally adopted in preference to all others. It has the great advantage of not implicating either the epiphysis or the joint. The operation is thus performed: The limb should be laid on its outer side on a sand bag, with the knee slightly flexed. A sharp-pointed scalpel is then introduced on the inside of the thigh, "at a point where the two following lines meet,—one drawn transversely a finger's-breadth above the superior tip of the external condyle, and a longitudinal one drawn half an inch in front of the adductor magnus tendon." The incision is made vertically upwards, and should be about three-quarters of an inch in length, being slightly longer than the breadth of the osteotome to be used. The scalpel must be carried directly down to the bone, and the osteotome must be inserted along it as it is withdrawn and then turned so that its cutting edge is at right angles to the incision and to the shaft of the femur. The femur is next divided for more than two-thirds of its thickness, the osteotome being taken in and out of the wound as little as possible. The mallet should have a heavy metal head and a short wooden handle. The cut in the bone must be parallel to the articular surface of the femur, which will be more oblique than natural, owing to the abnormal length of the inner condyle. The anterior and posterior layers of compact tissue must not be neglected, and when dividing the posterior extra caution must be used lest the osteotome should be driven into the popliteal vessels, an accident which has happened more than once. When two-thirds of the bone have been divided the remainder is fractured. If the patient be fully grown, and the bone of some size, two or three osteotomes may be used successively, the first being the thickest. The operation should be performed with all antiseptic precautions, and an antiseptic dressing should be applied after it. If the incision is made in the proper place no vessel requiring ligature is wounded. No sutures should be put into the wound unless it is of unusual size. The dressing may be left unchanged for one or two weeks, unless some discharge shows out from under it, as it may do at the end of the first twenty-four hours. After the operation the limb may be placed on any convenient splint for the first day or two, until it is seen if the dressing requires changing, after which a plaster of Paris bandage should be applied. The results of the operation have been extremely satisfactory. Up to July 31st, 1884, Macewen had operated on 804 limbs belonging to 409 patients, varying in age from 7

to 46. In 8 cases only did suppuration take place. In 5 cases the operation was followed by death, but in none of these was the fatal result directly due to the osteotomy, one dying of tuberculous meningitis, one of phthisis, two of diphtheria, and one of pneumonia, which had commenced before the operation was performed. The average duration of the treatment is about ten weeks, six in splints and four in hospital or at home learning to walk. The patient is usually fully restored to activity in three months from the time of operation.

Although Macewen's supracondyloid osteotomy is the operation which, at the present day, is the most extensively practised for genu valgum, some Surgeons prefer to divide the femur with a fine straight saw from the outer side. This is very readily done by making a small incision on to the outer surface of the bone with a narrow straight bistoury, which is carried across the front of the femur, in order to divide the periosteum. As the knife is withdrawn the saw is introduced, and the bone sawn from before backwards through about two-thirds of its thickness, the remainder being fractured. The line of division should have the same direction, but should be at a rather higher level than in Macewen's operation.

**Genu Varum, Genu Extrorsum or Bow-knee**, is the reverse of genu valgum. It is almost invariably the result of rickets, and is associated with rickety curves of the tibia and femur. It commences in early childhood, and may then be remedied by properly constructed splints. If not cured at this age, osteotomy may be required later on. It may be necessary to divide the tibia as well as the femur.

**Genu Recurvatum** is a rare congenital malformation in which the leg is in a position of over-extension. It is believed to be due to accidental extension instead of flexion of the lower extremities *in utero*. It is sometimes associated with spina bifida. In some cases the patella has been either imperfectly developed or absent. Great benefit, or even cure, may be effected by the early application of an apparatus gradually bringing the limb into the flexed position.

**CONTRACTION OF THE KNEE-JOINT.**—In this condition the knee is fixed in a flexed position, either temporarily by muscular action, or permanently by chronic changes in or around the joint. The pathological conditions which may occasion the deformity are very numerous, but independently of its cause two chief varieties are met with:—1. Simple flexion of the leg on the thigh, at a greater or smaller angle, and with more or less mobility according to the condition of the joint. 2. In addition to this, there may be horizontal displacement of the bones, the head of the tibia being thrown backwards, the femur and patella projecting more than is natural.

In examining a case of contraction of the knee-joint, the patient should be placed on his face, with the thigh extended. The leg on the affected side will then be raised more or less perpendicularly, and the amount of contraction may be accurately judged of by the angle that it forms with the thigh. The degree of mobility may also readily be ascertained.

In the consideration of this subject it will be convenient to deal separately with the three following conditions:—1. Contraction due to active inflammation of the knee.—2. Hysterical contraction.—3. Chronic contraction.

**Contraction from Inflammation of the Knee.**—In inflammation of the knee, the patient instinctively places the limb in the semiflexed position,

as being that in which there is least tension exercised on the structures that enter into the joint. This position, which is immediately assumed on the occurrence of acute and active inflammation in the joint, comes on more gradually in cases of subacute inflammation; and here the symptoms of disease in the joint may be so slight that the contraction may be considered the chief ailment, and engross the Surgeon's attention too exclusively.

The *treatment* of this variety of contraction consists in the treatment of the inflammatory condition of which it is the result. It is of the utmost importance that an inflamed knee should not be allowed to remain in a position of flexion, or the condition will readily pass into one of chronic contraction.

**Hysterical Contraction** is usually associated with other manifestations of hysteria, of which it is but a local symptom, and commonly occurs in girls and young women. In this form of contraction there is no evidence of disease within the joint; no redness, swelling, or other sign of inflammation; but there is great pain and tenderness about it. This pain, as usual in hysterical cases, is superficial and cutaneous. It is not confined to the articulation, but radiates to some distance beyond it. Any attempt at straightening the limb not only greatly increases the pain, but also calls the adjoining muscles into such forcible action that it is impossible to improve the position. These local symptoms are connected with the ordinary signs of a hysterical temperament, with spinal irritation, and often with uterine derangement.

The *treatment* of these cases of hysterical contraction of the knee is simple. The first thing to be done is to straighten the limb. This can be effected only by putting the patient under the influence of an anæsthetic, when, all sensibility being suspended, the muscular opposition, which is partly voluntary, and no doubt in some measure reflex, is no longer called into action, and the limb falls of its own accord almost into the straight position, in which it must be retained by means of a back splint, lest the retraction recur with returning consciousness; and then, the hysterical condition being removed by treatment directed to the improvement of the general health, the tendency to the return of the deformity will be obviated.

In some long-standing cases of hysterical contraction the deformity is not altogether relieved by relaxing the muscles with an anæsthetic. This results from the gradual shortening of the hamstring and of the fibrous structures about the back of the joint caused by the persistent flexion. Under these circumstances division of the tense hamstring tendons may be necessary (p. 548).

**Chronic Contraction.**—Under this heading are included those important cases in which the knee is permanently flexed and otherwise displaced as the result of structural changes in and around the joint. In severe cases the patient cannot put the foot to the ground, and the limb becomes useless for the purpose of progression. But a leg with a badly contracted knee is worse than useless—it is a positive incumbrance; the limb projects behind in a most awkward manner, swaying as the body moves round, constantly in the way and liable to injury. From want of use, the nutrition of the limb becomes impaired, the foot is cold, the circulation in it is languid, and the toes become liable to chilblains and troublesome ulceration. In the less severe forms of contracted knee, the inconvenience, though not so great as that just

described, is very considerable ; for, as the patient can never bring the heel or sole to the ground, he rests insecurely on the tips of his toes, and walks but unsteadily with the aid of a crutch or stick.

Although chronic contraction of the knee may arise from many different causes, the essential condition, which is common to all, is that the joint is allowed to remain in a position of prolonged flexion. As the result of this, those structures which are relaxed by flexion gradually become shortened and resist all attempts at extension. Among the structures thus affected may be mentioned the ligament of Winslow, the anterior crucial ligament, the hamstring muscles, and in extreme cases the skin of the popliteal space. In the majority of cases, however, the deformity is not limited to simple flexion, but is marked also by a varying degree of backward displacement of the head of the tibia and external rotation of the leg.

The partial dislocation backwards of the head of the tibia is largely the result of the prolonged flexion, for in this position the hamstrings act at a considerable advantage over the extensors, and will tend to draw the head of the tibia backwards into the ham (Fig. 643).

In cases in which the contraction results from inflammatory changes in the knee, this displacement of the tibia is partly dependent upon softening and consequent relaxation of the posterior crucial and lateral ligaments. The displacement relaxes the anterior crucial ligament, which gradually becomes shortened and offers the chief obstacle to extension.

Fig. 643.—Chronic Contraction of Knee-joint; Head of Tibia drawn backwards.

The external rotation of the leg which is so often also present is probably produced by different causes. It results in part no doubt from the natural tendency of the limb to roll outwards when the ligaments of the knee are relaxed, and may also be partly occasioned by the action of the biceps.

We thus see that in a well-marked case of chronic contraction of the knee the deformity is of a threefold character : flexion, displacement of the head of the tibia backwards, and rotation of the leg and foot outwards.

The most important division of these cases of contracted knee depends upon the presence or absence of osseous ankylosis.

In the majority of cases in which osseous ankylosis does not exist, the deformity results from *consolidation of the ligamentous structures* in and around the joint. When the contraction follows rheumatic inflammation the capsule and ligaments are the parts chiefly affected. When it follows tuberculous disease, as is indeed most common, the internal structures of the joint are more or less disorganised, and the deformity is maintained by firm fibrous adhesion.

In these cases the knee is usually fixed at or near a right angle, and is capable of but very limited motion. The hamstring muscles are not tense, unless the knee is extended to its utmost ; and, indeed, in some cases they are flaccid, and feel soft. Not unfrequently the leg can be extended up to a

certain point, with as much freedom as in the natural state, and then further movement is checked by a sudden stop. If this be not dependent on the tibia coming into contact with an ankylosed patella, it is owing to shortening of the ligaments or to the presence of adhesions in the joint.

In other cases the *hamstrings are contracted* either alone or in addition to the results of chronic inflammation within the joint that have just been described. In these cases the hamstrings will be found to be tight; and, in proportion as the leg is extended on the thigh, they will become more tense, until at last all further extension is resisted, apparently by their traction, and not by any sudden check or stop within the joint itself.

*Ossseous ankylosis* exists in only a small proportion of cases of chronic contraction of the knee. It may be met with in any case of contraction following acute or chronic disease of the joint which has caused destruction of the articular cartilage. It is especially apt to follow septic traumatic arthritis.

**Treatment of Chronic Contraction of the Knee.**—It is very essential that in the treatment of all inflammatory conditions of the knee the joint should be kept in the extended position, and thus the occurrence of permanent contraction avoided. Seeing also that the conditions present in a contracted knee and the diseases which lead to it are so various, it follows that no general line of treatment can be laid down which shall be applicable in all cases. It will be convenient to consider in the first place the treatment of those cases in which osseous ankylosis does not exist.

Extension of the limb will usually prove sufficient when there is simple angular contraction. This may be done either gradually by means of the screw-splint behind the knee, or forcibly and at once, under the influence of anaesthetics. I prefer the latter method, not only as being the more speedy, but as being perfectly safe and effectual. The mode of effecting forcible extension is as follows: The patient being fully under the influence of an anaesthetic, and lying on his face, the Surgeon, standing above him, seizes the foot of the affected limb with one hand, whilst with the other he steadies the limb just above the knee. He now extends the leg gradually but forcibly; as it comes forwards, the bands of adhesion in and around the joint will be felt and heard to give way with loud snaps and cracks, distinctly audible at some distance. Should there be much resistance within the joint, the Surgeon may apply his own knee or elbow to the upper surface, and thus increase the force with which the limb is acted upon. In this way I have never found any difficulty in effecting at once the extension of the limb. Nor have I ever seen any evil consequences result; indeed, it is surprising to what an amount of force a joint that has been contracted for any length of time may be subjected without inconvenience. Beyond some pain for a few days, and slight heat, easily subdued by evaporating lotions, I have never seen any ill results arise; but care must be taken that no inflammation is going on within the joint at the time of this manipulation, for, if this were present, the operation would certainly be followed by injurious results. After extension has been made, the limb should be fixed on a long splint, well padded, or on a Thomas's knee-splint, evaporating lotions applied, and the patient kept in bed for a few days, after which, with the aid of a starched bandage, he may walk about.

In those cases in which the flexion appears to be due to retraction of the hamstring tendons, these must be divided. The tendon of the biceps will usually be found to be the most tense, and should first be divided. The

semitendinosus next requires division, but it is rarely necessary to cut the semimembranosus. If subcutaneous tenotomy be practised the Surgeon should introduce the tenotome close to the side of the tendon to be divided, and cut in a direction from the popliteal space towards the skin. In dividing the biceps tendon great care must be taken not to injure the external popliteal nerve which lies to its inner side. This may be avoided by keeping the side of the tenotome well against the inner side of the tendon, then turning the edge outwards when passed deep enough. Any tense aponeurotic bands which are felt after the tendons have been cut should be left, as any attempt to divide them may bring the tenotome into undesirable proximity to the popliteal vessels, the anatomical relations of the parts often being considerably altered.

Division of the tendons by the open method—that is, by making a short incision over them—has the advantages that the risk of injury to vessels or nerves is avoided, and the Surgeon may safely proceed to divide any tense fascial bands which become prominent after the tendons themselves have been cut through.

After division of the hamstrings, the knee does not commonly come readily into the straight position, owing to the shortening of the ligament of Winslow and the anterior crucial ligament, and gradual extension, by means of proper apparatus, will be required to overcome this and to stretch the adhesions within and around the joint.

In a large proportion of cases of contracted knee, flexion of the joint is associated with backward displacement of the head of the tibia and external rotation of the leg. Simple extension will then be insufficient to rectify the deformity, for although the flexion may be overcome the displacement of the tibia remains, and the limb is left in the condition represented in the accompanying diagram (Fig. 644).

Various mechanical contrivances have been suggested for drawing forward the tibia into its normal position on the end of the femur, but it is not surprising that little success follows their use, for, as we have seen, the movement forwards of the bone is strongly resisted by the shortened anterior crucial ligament.

If, therefore, the contraction be sufficiently marked to interfere seriously with the use of the limb operative interference is necessary. The operation will consist in carrying out the usual steps required in excision of the knee. The joint must be opened by freely dividing the contracted ligaments and fibrous adhesions, and then sufficient bone must be removed to allow the parts to be brought into a satisfactory position. In practice it sometimes happens that this operation is undertaken for contraction of the knee due to tuberculous disease which is not yet entirely quiescent. In such cases the excision serves the double purpose of removing the diseased tissues and remedying the deformity.

The only remedy for *osseous ankylosis of the knee in a contracted position* is an operation. Rhea Barton, of Philadelphia, in 1835, proposed an operation for restoring the straight position of the limb in cases of complete osseous

FIG. 644. — Knee-joint after Extension: Head of Tibia thrown Backwards.

ankylosis of the knee-joint with angular deformity. The proceeding consists in excising a wedge-shaped piece of the shaft of the femur above the condyles, not including the whole diameter of the bone, then fracturing the undivided portion, and so bringing the limb into a straight position. Buck, of New York, in 1844, modified this operation by sawing out a wedge-shaped portion, consisting of the condyles of the femur, the patella, and the head of the tibia. In one case, that of Reil, the femoral artery had to be tied for secondary hæmorrhage from the popliteal on the fifteenth day; but the patient made an excellent recovery with a useful limb. Brainard of Chicago, in 1854, proposed a simple method for remedying angular osseous ankylosis of the knee, which before the introduction of the antiseptic treatment of wounds was preferable to the open methods. It consisted in drilling the femur subcutaneously and then fracturing the bone. This operation was first done by Pancoast in 1859, and subsequently by Brainard, Gross, and others, who extended it to subcutaneous perforation of the joint and to separation of the patella.

At the present day the only operation which is practised for angular osseous ankylosis of the knee is antiseptic osteotomy. The method adopted must depend upon the position of the limb. If the flexion is considerable a wedge-shaped piece should be removed from the lower end of the femur with a saw or osteotome; the width of the base of the wedge being proportional to the amount of flexion. In order to avoid any risk of wounding the popliteal vessels it may be advisable not to penetrate the whole thickness of the femur, but to leave the posterior layer of compact tissues to be subsequently fractured, as practised by Barton. If the flexion be less marked simple osteotomy of the femur may be sufficient, or it may also be found advisable, according to Volkmann, to cut through the tibia just below its head. The most suitable incision in these cases will be found one extending across the prominent end of the femur from one condyle to the other. The methods of adjusting the bones and the subsequent treatment are the same as after excision of the knee (p. 452).

**Ankylosis of the knee in the straight position** interferes comparatively little with the utility of the limb. It is, however, desirable, when practicable, to restore the mobility of the joint. The possibility of doing this will depend on the degree of ankylosis. If this be osseous, or even densely fibrous, little can be done; but if the rigidity depend chiefly on condensation of the capsule, and fibroid induration outside the joint, much may be effected by the use of properly constructed apparatus. This should be of two kinds: 1. A leg-and-thigh piece securely laced on to the limb, having an angular joint opposite the knee, and connected posteriorly by a strong band of vulcanized india-rubber, the elastic tension of which is constantly striving to overcome the straightened limb by flexing it backwards; and 2. a similar apparatus, with rack-and-pinion, instead of elastic, by which the knee can be forcibly flexed once at least in the day.

Ankylosis of the knee in the *angular position forwards*, so that the leg is over-extended upon the thigh, is very rare. Indeed, I am acquainted with only three preparations illustrating this deformity—one in the museum of University College, one in that of St. Thomas's Hospital, and another exhibited by Adams to the Pathological Society, from a limb amputated by Grant of Canada, in which this condition occurred to a young man as a consequence of a wound of the joint some years previously.

**Deformities of the Bones of the Lower Limb from Rickets.**—The distortions of the bones of the leg arising from rickets have already been alluded to in the chapter on diseases of bone (p. 303). The condition which usually requires treatment is that in which the lower part of the tibia is strongly curved in a direction forwards and outwards, or less commonly directly forwards.

In young children operation is very rarely required, and the local treatment should consist in preventing walking by the application of a well-padded thin wooden splint from the knee to below the foot and in daily douching and rubbing. By these means the increase of the deformity may be prevented and a most satisfactory result obtained, the curvature being gradually lessened by the moulding action of the muscles. If, however, the deformity be extreme, it may be safely treated by snapping through the soft rickety bone under chloroform and fixing the limb on a straight splint. This treatment is, however, rarely required.

In older children osteotomy of the tibia may be required if the deformity is sufficient to cause disfigurement and interference with the use of the limb. In the majority of cases it is sufficient to divide the tibia at the point of greatest curvature with an osteotome or fine saw, through a short incision along its anterior border. The removal of a wedge-shaped piece of bone is a more formidable proceeding, and is rarely required except when the curvature is very marked.

If necessary, the same bone may be divided in more than one place, either simultaneously, or the second operation may be deferred till the patient has recovered from the first. In complicated cases of knock-knee with rickety curves of the femur and tibia, Macewen has performed as many as ten osteotomies simultaneously on the same patient. If proper antiseptic precautions are adopted, the danger of these operations is very slight, as may be seen from the result of Macewen's practice (p. 544).

**CLUB-FOOT. TALIPES.**—The deformities classed together under the name of club-foot or talipes may be either congenital or acquired, and apart from their causation they are divided according to the position which the foot assumes.

There are four primary varieties of club-foot, and two secondary ones. Of the four *primary* forms, in two the deformity is in the antero-posterior direction, in the sense of flexion and of extension: **Talipes Equinus**, in which the heel is drawn up and the toes pointed downwards (Fig. 645); and its antithesis, **Talipes Calcaneus**, in which the heel is pointed downwards and the foot and toes drawn up (Fig. 646). In the remaining two forms the deformity is lateral, the foot being adducted and twisted inwards in **Talipes Varus** (Fig. 647), and abducted and twisted outwards in **Talipes Valgus** (Fig. 648). These four primary forms of club-foot correspond with and are dependent on a permanent condition of one or other of the four simple movements of which the foot is susceptible at the ankle-joint.

Besides these four primary forms, there are two secondary varieties of club-foot: **Talipes Equino-varus**, in which the heel is raised and the foot drawn inwards; and **Talipes Calcaneo-valgus**, in which the heel is drawn down and the foot turned out. The association of Talipes Equinus and Varus has been explained by supposing that it is due to contraction of the muscles supplied by the internal popliteal nerve, especially the gastrocnemius and soleus

and the tibialis posticus, and in the same way Talipes Valgus and Calcaneus are associated, because in these the extensor and peroneal muscles supplied from the external popliteal are the seat of contraction. That this is the case in certain acquired cases is undoubted, but there is no evidence that these nerves are in any way affected in cases of congenital club-foot.

In considering the subject of club-foot, it will be convenient to describe

Fig. 645.—Talipes Equinus.

Fig. 646.—Talipes Calcaneus.

the congenital and acquired forms separately, more especially as the treatment differs considerably in the two cases.

**Congenital Club-foot.**—Any of the varieties of club-foot which have been enumerated above may be present at birth, but of all forms, **talipes equino-**

Fig. 647.—Talipes Varus.

Fig. 648.—Talipes Valgus.

**varus** is by far the most common, constituting, according to R. W. Parker, from 90 to 95 per cent. of the congenital cases.

**Causation.**—Three chief theories have been brought forward in explanation of congenital club-foot. According to one view the deformity is due to changes in the nervous system which give rise to spasm or paralysis of certain groups of muscles. This explanation is doubtless correct in some cases, especially in those in which the deformity is associated with spina bifida, but it seems quite

certain that it is not true of all. Not only is there no evidence at birth in the majority of cases either of spasm or paralysis, but, as has been shown by Parker and Shattock, a most careful microscopic examination of the nervous centres, the nerves, and the muscles, fails to show any structural abnormality. The view also that the talipes results from primary changes in the bones can be true only of very exceptional cases, for although deviations from the normal shape of certain of the tarsal bones may be present, it seems clear that these are secondary to the malposition of the foot and not the cause of it.

The third theory, and that which is at the present time almost generally accepted, is that the deformity results from mechanical causes acting upon the foot *in utero*. It is well known that the normal position of the feet in the early periods of intra-uterine life is one of inversion, and, as Parker and Shattock express it, if the inversion "be maintained beyond the normal period of time, the muscles and ligaments will as a consequence be adaptively short on one aspect of the limb, and too long on the other; a normal position of inversion will become a deformity." This view readily explains the relative frequency of talipes equino-varus. According to the same theory congenital talipes calcaneus is the result of "an exaggeration by environment of the position natural to the foetal feet during the later period of intra-uterine life, some limitation of extension movement being normal at the time of birth." Among the conditions which may be supposed to act mechanically upon the feet in this way are malposition of the foetus and undue pressure of the wall of the uterus, due possibly to a deficiency of the liquor amnii. The results of treatment support the mechanical theory and are opposed equally to the so-called nervous and osseous theories, for many of the slighter cases can be cured by means directed to place the foot in its normal position and retain it there. Talipes may affect one or both feet, and may occur in either sex, but appears to be more common in boys than in girls.

On account of the fact that talipes equino-varus is much more common than any other variety of congenital club-foot, this form will be described fully, and the other varieties will afterwards be briefly mentioned.

In **Congenital Talipes Equino-varus** the foot is twisted inwards, the inner side of the sole is raised, and the concavity of the arch of the foot is greatly increased. At the same time the heel is drawn upwards to a varying extent and the tendo Achillis is tense. The skin at the inner border of the foot is contracted and transversely wrinkled, whilst that on the outer side is loose and redundant. When the child is old enough to stand it will be found that only the outer border of the foot comes into contact with the ground, the skin covering the tarsal end of the fifth metatarsal bone becomes dense and firm, and a bursa forms beneath it (Fig. 647). The astragalus and os calcis maintain their normal relations to each other, and are more or less adducted. The chief displacement is at the transverse tarsal articulation between the os calcis and cuboid, and the astragalus and scaphoid. The anterior part of the foot is in a position of extreme flexion, adduction, and rotation inwards, amounting in many cases to partial dislocation. A great part of the head of the astragalus which should be normally in contact with the scaphoid is thus uncovered, and forms a prominence beneath the skin. In old cases the cartilage of the head will be found to have disappeared, its place being taken by a layer of dense fibrous tissue. The bones in front of the transverse articulation maintain their normal relation to each other. The muscles that

are shortened in this position of the foot are chiefly the *tibialis posticus*, *tibialis anticus*, and the muscles of the calf inserted into the *tendo Achillis*.

**Pathological Anatomy.**—A careful study of the changes met with in congenital talipes equino-varus is essential to the proper treatment of the deformity, and our knowledge of this subject has been much increased by the researches of Parker and Shattock. The muscles are healthy unless the case be one of old standing, when they will be found to be atrophied generally from disuse. The directions of the tendons is necessarily altered, and those muscles which are relaxed by the abnormal position of the foot become shortened. Thus the *tendo Achillis* and the tendons of the *tibialis anticus* and *tibialis posticus* become tense when an attempt is made to rectify the position of the foot, but Parker and Shattock have shown that all these may be dissected away, and in fact all the soft parts except the ligaments, without materially diminishing the deformity. The most important fact which we owe to these observers is that the ligaments take the chief share in maintaining the abnormal position of the

foot. "The ligaments chiefly at fault are those placed on the inner border of the deformed foot, namely, the anterior portion of the internal lateral ligament of the ankle, the astragalo-scaphoid and the calcaneo-scaphoid ligaments, all three being blended together into one indistinguishable capsule of great strength." In more severe cases which have been walked upon, the long and short plantar ligaments are shortened, as is also the plantar fascia, and in extreme cases the skin of the sole may be insufficient to allow of full extension of the contracted arch of the foot. The bones of the foot are not necessarily altered, but various changes in the shape of the articular surfaces may result from their altered position. Of all the bones

Fig. 649.—Bones in Talipes Varus.

the one which is most commonly altered is the astragalus, the obliquity of the neck being considerably increased, as the result of the inversion of the front part of the foot. The extended position of the ankle-joint leads to an undue extension of the superior articular surface of the astragalus backwards, whilst in front the surface is lessened. If the varus be of old standing, the astragalus will generally be found to be atrophied more particularly about its head, and the navicular and cuboid bones may have suffered similar changes.

**Treatment of Congenital Talipes Equino-varus.** In the consideration of this subject it is very necessary to distinguish clearly between those methods which are available for ordinary cases in which the treatment is commenced in early infancy, and the more severe measures which may be required in obstinate or neglected cases.

In young children extensive operations are rarely necessary, and are usually quite unjustifiable, for with patience excellent results can as a rule be obtained by simple means.

Regarding the congenital deformity as the result of prolonged malposition of the foot, the principle of treatment must be the correction of this by manipulation and the use of suitable splints, aided, if necessary, by the division of resisting structures. As soon as possible after birth the treatment

should be commenced by frequently moulding the foot into the best position into which it can be drawn. By this simple means alone some of the slighter cases may be entirely cured. In the large majority of cases, however, other measures are required, and the following method will often be found most satisfactory. A straight splint of block-tin is prepared, as suggested by Little, long enough to reach from the knee to slightly beyond the toes, and about an inch and a half in breadth. The splint is completely covered with soft wash-leather. It is then moulded to the outer side of the leg and foot and secured with a narrow bandage, the foot being placed in the fully extended position. The inversion of the foot is gradually corrected by bending the lower end of the splint outwards day by day, until, if possible, the position of inversion is replaced by one of slight eversion. The splint should be removed daily, and the foot thoroughly rubbed and manipulated. By this means the inversion of the foot is cured and the case converted into one of simple talipes equinus, which may sometimes be remedied by applying a block-tin or thin wooden splint with a rectangular footpiece. As a rule, however, *division of the tendo Achillis* is the most ready way of remedying the extension of the foot. The limb should be placed on its outer side. The assistant then relaxes the tendon slightly while the Surgeon slides a tenotome beneath it from the inner side; the assistant then makes the tendon tense, and the Surgeon proceeds to divide it, using the knife as a lever, the fulcrum being the edge of the malleolus. The Surgeon must keep the fingers of his left hand on the tendon to feel that the knife does not approach the skin too closely. As the section proceeds he will hear the tendon creaking as its fibres are successively cut through. The division may safely be made from the cutaneous surface if it be preferred. The tendon must be made tense, and the point of the tenotome entered through the skin close to its anterior surface; the foot is then fully extended, while the Surgeon pinches up the skin, and passes the tenotome between it and the tendon. He then turns the edge of the knife to the tendon, while the assistant forcibly flexes the ankle. No sawing or free cutting is required if the knife have been entered sufficiently far forwards. Unless care be taken in cutting though the tendo Achillis, there is also some risk of wounding the artery; as, in bad cases of varus, these two structures lie close together, the tendon being drawn out of the median line towards the inner ankle. In one instance I have seen the posterior tibial artery punctured in an attempt to divide some tense bands that lay beneath this tendon; the bleeding, which was very free, was, however, readily stopped by firm pressure by means of a pad and bandage over the bleeding orifice. Tamplin states that he has seen no ill effects follow this accident. If a circumscribed traumatic aneurism form, it must be laid open, the clots turned out, and the vessel tried. After the tenotomy the foot should be fixed on a rectangular splint, which should be readjusted at least once a day, and the manipulation continued.

The treatment here described is thus seen to include two stages: first, the correction of the varus by the use of splints; and secondly, the correction of the equinus by division of the tendo Achillis. In mild cases the position of the foot can be gradually corrected by the application of a plaster of Paris bandage, which is reapplied every ten days or a fortnight. This has, however, the disadvantage that the plaster cannot be removed for the employment of manipulation.

In a considerable proportion of cases the inversion cannot be corrected until the tense structures which maintain it have been divided. The treatment adopted for this purpose has been considerably modified of recent years as the result of the recognition of the fact that the ligaments of the inner border of the foot play a much more important part than the muscles in maintaining the deformity. Accordingly, the division of the tendons of the tibial muscles above the ankle has been replaced by the more efficient method of dividing the tense ligaments in the foot itself, and by a single operation bringing the foot into the best possible position.

The method of dividing the ligaments which are chiefly at fault is thus described by R. W. Parker. A curved tenotome with a short cutting blade (Fig. 650) "should be entered immediately in front of the anterior border of the internal malleolus, the blade as far as possible being kept between the ligaments to be divided and the superjacent skin. The blade is then turned against the surface of the ligament, and, by means of a gentle sawing action, is made to divide it. As the superficial fibres are divided, deeper ones come into play, and must in their turn be divided until bone is reached. By

Figs. 650, 651, 652, 653.—Tenotomes for Division of Tarsal Ligaments (Parker).

keeping the knife close to the bones and directing its point towards the plantar aspect, the calcaneo-scapoid ligament can easily be divided. In this operation the tendon of the tibialis posticus will almost certainly be cut, and not improbably that also of the tibialis anticus. The long and short plantar ligaments can most effectually be reached just where they pass between the two bones. A straight tenotome (Fig. 651) must be entered as nearly as possible over the calcaneo-cuboid articulation on the outer edge of the foot. If there be much inversion this point will appear to be on the sole of the foot. The blade must be kept close to the bone and made to follow the direction of the

articulation. In this manner, the two ligaments, mostly blended together at this point, will be divided simultaneously." In cases in which the extension of the foot is extreme, Parker finds it sometimes useful to divide the posterior ligament of the ankle-joint. "This is best accomplished by means of a small spear-headed knife (Fig. 653), which should be passed through the tendo Achillis in the direction of its fibres, and then turned flatways, and passed through the posterior ligament about its middle, cutting first on one side and then on the other." After the operation the foot should be fixed in plaster of Paris in the best attainable position for about a fortnight. The plaster should then be removed and a light wooden splint with a rectangular foot-piece applied and taken off daily in order that rubbing and manipulation may be practised. Complicated appliances, such as "Scarpa's shoe" and "Aveling's talivert," which are intended to correct the deformity by the action of screws and joints, have been largely abandoned in favour of simple splints of tin, wood, or plaster of Paris.

In 1884, Phelps of New York brought forward a more radical method for the

division of the tense structures at the inner border of the foot. This consists in making a free vertical incision across the inner border of the foot, over the position of the astragalo-scapoid articulation, which is indicated by a fold in the skin due to the inversion of the foot. The incision is deepened to the bones and the astragalo-scapoid joint freely opened. In this way all resisting structures can be freely divided, the most important being the two tibial tendons, the inner part of the plantar fascia, the front portion of the internal lateral ligament of the ankle, and the inferior calcaneo-scapoid ligament. The tendo Achillis is divided subcutaneously. When the operation is completed

the foot can be drawn outwards without force into a slightly everted position. The widely gaping wound is then carefully packed with antiseptic gauze and the foot fixed in suitable splints, preferably of plaster of Paris. Owen, who has strongly advocated this operation in suitable cases, recommends that the first dressing should not be changed for ten days or a fortnight. The operation has been performed in several hundred cases by Phelps and others, but no death or serious accident has so far been recorded. The method should, however, be reserved for cases in which simpler measures have failed, but it certainly presents advantages over many of the severe operations presently to be described.

Although, with the exception of the tendo Achillis, individual tendons rarely

require separate division in the treatment of congenital talipes varus, it will be well to describe here the methods by which the tendons of the *tibialis posticus* and *tibialis anticus* may be divided if necessary.

In the section of the *tibialis posticus* tendon behind the ankle, there is much danger of wounding the posterior tibial artery, which lies close to it.

The best way to avoid this vessel is, as Tamplin recommends, to puncture the sheath with a sharp tenotome introduced close to the tibia, immediately above the malleolus (Fig. 654). In adults or young children past the age of infancy, a small point of bone can be felt in this situation, which marks the upper limit of the groove in the malleolus in which the tendon lies. The puncture should be made above this, otherwise the knife cannot be passed under the tendon. After the sheath has thus been opened by a puncture, a blunt tenotome is introduced, care being taken not to use so much force as to push it through the sheath on the opposite side. The tendon is then divided in the usual way. If the operation be performed too high up the limb, the *flexor longus digitorum* will be divided with the tendon of the *tibialis posticus*, but this is a matter of little moment.

The *tibialis anticus* must be divided at the point marked in Fig. 654. The tenotome must be passed from the outer side to avoid any risk of wounding the dorsal artery of the foot.

In spite of all treatment, however, a considerable proportion of cases of congenital talipes equino-varus are at most only partially relieved. In such cases, as the child grows up the muscles fail to develop, and the bones become altered in form so as to adapt them to their abnormal position. In such extreme cases, various operations have been recommended to enable the patient to bring the sole of his foot to the ground. Many years ago Little suggested the removal of the cuboid in order to assist in overcoming the adduction of the anterior part of the foot. This operation was performed with success by Solly in 1857, but did not come into general use. In 1872, Lund of Manchester removed the astragalus from each foot of a child, with the result of obtaining considerable improvement in the position of the feet. In 1876, R. Davy repeated the operation in several cases, obtaining good results, but was not able to dispense with prolonged use of apparatus afterwards. In 1876, Davies-Colley recorded a case in which he removed a wedge-shaped piece of the tarsus of sufficient size to allow of the anterior part of the foot being brought into a straight line with the posterior. The operation was performed by a long incision on the outer side of the foot from the middle of the *os calcis* to the middle of the fifth metatarsal bone. From the middle of this another was carried across part of the *dorsum*. The cuboid was first excised, after which a wedge-shaped portion of the tarsus was removed "without paying any regard to its articulations." The bones taken away included the whole cuboid, parts of the *os calcis*, and of the three cuneiform bones, nearly all the scaphoid, and a part of the astragalus. R. Davy commences by removing an oblong piece of skin from the outer side of the foot including the false bursa. He then makes a vertical incision on the inner side of the foot in the deep crease that is always present, and of sufficient length to include the thickness of the scaphoid bone. The soft parts are next raised from the *dorsum* and a "kite-shaped" director specially designed for this purpose is passed between them and the bones. The tarsus is then divided by means of a probe-pointed saw which is guided at first by two

grooves in the under surface of the director. It is most convenient to divide the distal side first. The soft parts are then cleaned from the under surface of the wedge of bone by means of a blunt knife or elevator, and the wedge removed in one piece. If the heel is much drawn up, the tendo Achillis can be divided after the operation. Davies-Colley found the most convenient apparatus during the early part of the after-treatment, to be "a back-splint extending from the middle of the thigh to within four inches of the heel. To the distal end of this was fastened a transverse bar of wood, terminating on either side in short upright bars, to which the fore part of the foot was attached by means of strapping." R. Davy uses a splint made of two iron rods fixed to the lower part of the thigh and upper part of the leg by a plaster of Paris bandage. The lower end of each rod is cut into a screw. A foot-piece fixed on a transverse iron bar with a ring at each end slides over the two rods and is fixed by a washer and thumb-piece on each side. The foot-piece is fixed by a pivot and screw to the transverse bar and can be rotated so as to evert the anterior part of the foot. The results of these operations have been very satisfactory. In Davies-Colley's case the patient could jump and hop six months after the operation. Davy has performed the operation in twenty cases with only one death. It is evident, however, that such an operation can be justifiable only when all other means have failed, and can very rarely be required in young children.

H. P. Symonds instead of removing any bone merely divides the tarsus transversely at the level of the transverse articulation by means of a chain saw passed close to the bones. In this way he has obtained excellent results.

All other varieties of congenital club-foot are comparatively rare. Tamplin stated that congenital **talipes equinus** was unknown, but a few undoubted cases have been recorded. **Talipes calcaneus** is much less rare and is sometimes associated with spina bifida. The deformity can usually be corrected by manipulation and the application of a metal splint to the front of the leg and the dorsum of the foot. In some cases it may be necessary to divide one or more of the tendons which pass across the front of the ankle. Pure **Talipes Valgus** is rarely present at birth although a varying degree of inversion is often present in association with calcaneus, forming the variety known as *Calcaneo-valgus*. The treatment must be carried out upon the same lines as in other forms.

**Acquired Club-foot** may develop at any age but it is most commonly met with in young children, as the result of paralysis of certain muscles or groups of muscles, the foot then being drawn out of position by the uncontrolled action of their opponents. In later life displacement may be the result of the gradual shortening or "contracture" of the muscles that is not uncommonly met with in hemiplegia. These causes are central, but similar deformities frequently result from wounds or other injuries of the nerves supplying the muscles, or from diseases or injuries of the muscles themselves, accompanied by loss of substance and consequent shortening.

The changes which take place in the foot consist chiefly in the shortening of those tendons and ligaments which are relaxed by the abnormal position. The bones are normal (Fig. 649), except in extreme cases in which gradual alterations in their shape may occur. In paralytic cases the affected muscles show the ordinary appearance of atrophy and degeneration.

The most common forms of acquired club-foot are **talipes equinus** and

talipes valgus; the former being frequently associated with more or less varus.

*Talipes equinus* may result from the unopposed action of the calf muscles when the anterior muscles of the leg are paralysed, or from subsequent contraction of the former when themselves paralysed. It may also come on from some disease, such as an abscess in the calf by which the gastrocnemius is contracted and crippled. *Talipes valgus* or *calcaneo-valgus* is met with in its most marked form when the muscles of the calf, the tibialis posticus and the flexors of the toes are paralysed. The foot is everted, the arch is obliterated, so that the sole becomes flattened.

The anterior part of the foot is displaced outwards at the calcaneo-cuboid and astragalo-scaphoid articulation, and the scaphoid is partially dislocated outwards, so that the head of the astragalus projects at the inner side of the

Fig. 655.—Bones in Acquired Talipes Equinus.

Fig. 656.—Apparatus for use after division of tendo Achillis for Paralytic Equinus.

foot. The projection of the heel backwards is obliterated, and the outer side of the foot curved round so that the little toe is approximated to the point of the heel.

In extreme cases of calcaneo-valgus, the arch of the foot is sometimes increased, the heel being pointed down, and the foot sharply bent at the transverse medio-tarsal articulation, so as to bring the toes to the ground.

I have met with a case of *Talipes calcaneus* in a girl twelve years of age, in whom it was the result of contraction of the extension consequent upon loss of power in the flexors. A minor degree of this affection consists in a peculiar projection upwards of one or two of the toes, associated with some tension of the extensor tendons; by dividing these, and keeping the foot on a flat splint, the deformity may commonly be corrected. In some cases, however, the toe is so prominent, and the contiguous ones are squeezed under

it in such a manner, that the foot is completely crippled, and amputation of the displaced digit is required in order to restore the utility of the member.

In the **Treatment** of paralytic club-foot every endeavour must be made to prevent the occurrence of the deformity by maintaining the foot in a correct position, and in cases of infantile paralysis in which the muscles still react to the constant current, by the use of electricity and massage. When the faulty position is caused by permanent contraction of a paralysed muscle tenotomy may be practised, but the operation can be productive of nothing but increased loss of power if the talipes results from the unopposed action of the healthy muscles. In the latter cases the position of the foot may be improved by applying elastic extension in such a way as to exert traction in the direction of the paralysed muscle. This method, which is also applicable to congenital cases, was suggested by Barwell, and has been largely employed by Wright of Manchester. A light metal splint with a hook attached is secured to the front of the leg. The "artificial muscle," which consists of an india-rubber cord, is attached by one end to a strip of strapping surrounding the centre of the foot, and by its other end to the hook on the leg splint. In a case of valgus the strapping would be carried round the foot from within outwards and the india-rubber band attached to its extremity at the inner border of the sole.

In many cases the position of the foot must be maintained by the use of light iron supports. A method of treatment which is deserving of further trial in suitable cases consists in excising part of the tendon of the paralysed muscle and suturing the ends. This has been practised with success by Willett, Walsham and others on the tendo Achillis.

**Flat or Splay Foot.** **Spurious Talipes Valgus** is a condition frequently met with in young adults. It is predisposed to by those constitutional conditions that have already been described as favouring the development of lateral curvature of the spine, with which it is often associated, but the determining cause is most frequently over-fatigue of the foot from long standing, and from carrying heavy weights, or from a slovenly habit of walking by sliding rather than raising the feet, or twisting the foot so as to press upon the inner side. Girls of a tender age who are allowed to carry infants, boys set to heavy work beyond their strength, shop-boys and girls mercilessly kept upon their feet for too many hours, will early develop this deformity. When both feet are affected, there is usually knock-knee. In some instances flat-foot seems to be predisposed to by rheumatism, and it has been observed as a sequel of gonorrhœal rheumatism. The deformity is due to a weakness of the muscles in the sole of the foot, and to relaxation of the ligaments by which the arch is maintained, especially the long plantar, and the inferior calcaneo-navicular ligaments. As the result of this, the arch of the instep gradually sinks, so that the sole becomes perfectly flat. As the disease advances, a tendency to eversion of the foot takes place. At the same time, owing to flattening out of the arch, the inner side of the foot becomes lengthened, while the outer side, which is naturally only slightly arched, is but little altered. In consequence of this, the anterior part of the foot in front of the medio-tarsal articulation is displaced outwards. The scaphoid is thus partly dislocated from the head of the astragalus, which projects at the inner side of the foot, and being pressed upon, is often a source of much pain. The transverse ligamentous structures that bind together the bases of the metatarsal

bones at their digital ends become weakened and stretched. The consequence of this is, that the gait loses its elasticity, becomes shuffling, and the foot easily tires in walking.

In addition to the pain over the head of the astragalus, pain is often referred to the outer side of the ankle or to the metatarso-phalangeal joint of the great toe. The former is thought to be caused by the pressure of the malleolus on the outer surface of the os calcis and the latter by the altered relations of the joint due to flattening of the inner border of the foot. As Roth has pointed out, the pain is often most severe in cases in which the deformity is as yet little developed.

The *treatment* consists, in the first place, in improving the general health and removing the causes of over-fatigue or strain of the foot, without which surgical treatment may be of little avail. In very mild cases, careful attention to the boots may suffice to give relief. They must be wide at the toe, the heel must be large, and not too high, and made to extend on the inner side to a point opposite the middle of the foot. The boot must be fitted with a "valgus

Fig. 657.—Little's boot for Flat foot—right side.

Fig. 658.—Little's boot for Flat foot—right side, seen from behind.

pad," that is to say, a soft pad of cork, or better of india-rubber, placed inside the boot on the inner side in such a position as to support the natural arch of the foot. It is very important that the pad should not be too stiff or too large. The upper leathers must be strong, reach well above the ankle, and be firmly laced. If the feet are habitually cold, they must be rubbed twice a day with salt and water and warmly clothed. Methodical exercise of the muscles of the leg and foot, as recommended by Roth, forms an important part of the treatment. The most useful exercise consists in walking on the toes with the heels slightly raised from the ground. Roth instructs the patient to walk fifty steps in this way before and after each meal. Massage is also useful in some cases.

In more severe cases the apparatus represented in Figs. 657 and 658, known as Little's boot, will be found most effectual. It consists of an inner sole to the boot, fitted with a valgus pad. On the outer side is a steel spring fixed to a plate, which extends in the sole from the heel nearly to the middle of the instep. The upper end of the spring takes its bearing from a curved pad which rests against the leg about three inches above the ankle. In the lower part of the spring is a hinge to allow of the free movement of the ankle-joint.

The whole is included in the boot, and, beyond making the ankle look a little clumsy, hardly shows externally. The tendency of the apparatus is constantly to push the foot a little inwards, while at the same time it interferes with no movement of the joint, and gives every muscle free play. As the foot improves under its influence, any tendency to knock-knee which may have existed will also diminish, if not disappear. When wearing this apparatus the patient, if a child, may be allowed to run and play without restriction. It very rarely fails either to cure or greatly relieve the condition. Walsham recommends the use of a rubber band to support the arch of the foot. A leg-iron fixed to the outer side of the boot is secured at its upper end to the leg below the knee with a broad leather strap. The rubber band is attached to the outer border of the sole of the boot, and passing between the boot and the sole of the foot, is carried upwards along the inner side of the leg to be attached to the circular leather strap.

Various operations have been performed for extreme flat-foot. Golding-Bird has removed the scaphoid alone, and in other cases excised also the head of the astragalus; Ogston has excised the articulation between the astragalus and scaphoid, fixing the sawn surfaces with ivory pegs. These operations have relieved the patient's pain although not necessarily restoring the arch of the foot. Trendelenburg has practised supra-malleolar osteotomy of the tibia and fibula, by which the outward displacement of the foot can be corrected. Operation can never be justifiable unless all other methods have failed and the patient is seriously crippled by the deformity.

**Hollow Claw-foot.** This deformity is characterized by an increase in the normal antero-posterior arch of the foot, as the result of which the measurement from the toes to the heel is proportionately diminished. The toes themselves exhibit a remarkable displacement. The metatarso-phalangeal joints are over-extended, often to such an extent that the bases of the first phalanges are subluxated on to the dorsal surface of the necks of the metatarsal bones; the inter-phalangeal joints are flexed. The heads of the metatarsals project prominently in the sole, and painful corns often form over them. On the dorsal surface of each toe, in a position corresponding to the flexed joint between the first and second phalanges, the skin becomes thickened and false bursæ are often present. The tendons of the extensors of the toes are tense and stand out prominently as they pass over the hyper-extended metatarso-phalangeal joints. In nearly all instances the ankle is in a position of slight extension, or, at least, full flexion of the foot is impossible. This is due to a varying degree of tension of the tendo Achillis. The muscles of the leg will be found to be smaller than those of the opposite limb, when, as is often the case, the deformity is unilateral; the muscles of the calf are chiefly affected. In a well marked case of hollow claw-foot any attempt to reduce the arching of the foot is resisted by the shortened plantar fascia and ligaments, which form tense bands at the inner part of the sole.

This deformity makes standing and walking very painful when too prolonged; for this reason, that from the position of the toes and from the increased arch of the foot, the whole pressure in walking is borne upon the heel and upon the skin covering the unnaturally prominent heads of the metatarsal bones.

In the case from which the drawing (Fig. 659) was made, the condition was congenital, but did not trouble the patient till he was ten years old. When he was apprenticed, a long walk always gave him pain, and at last he was

obliged to lie up about one week in every month to get rid of his pains. Both feet were affected, but the left much less than the right. By galvanic examination, irritability was found to be lost in the right interossei and very much diminished in the left.

The **Mode of Production** of *pes cavus* is very doubtful. Duchenne explains it as being the result of paralysis of the interossei and of the short flexor and adductor of the great toe. As in the hand, the interossei not only move the toes laterally, but they powerfully flex the first phalanges, at the same time that they extend the two last. According to Duchenne, the origin of hollow claw-foot is as follows :—

“When the interosseous muscles are paralysed or atrophied, the tonic contraction of the muscles which extend the first phalanges and that of the muscles which flex the last phalanges being no longer opposed, the claw-like condition of the toes gradually becomes augmented. The posterior extremities of the first phalanges are subluxated upon the heads of the metatarsal bones ; then the curve of the plantar arch becomes increased and the plantar fascia shortened ; then certain articulations and their ligaments become deformed,

as in all club-feet.” The mechanism is exactly the same as that of the similar disease in the hand.

Fig. 659. — Hollow Claw-Foot. *Pes Cavus*.

as in all club-feet.” The mechanism is exactly the same as that of the similar disease in the hand. The disease is always accompanied by a tendency to *talipes equino-varus*, “that is to say, the flexion of the foot upon the leg during walking is incomplete, and during this flexion of the foot the *tibialis anticus* (flexor and adductor) has a predominance of action over the *extensor longus digitorum* (flexor and abductor of the foot) ; or in other words, during flexion, the sole of the foot is turned slightly inwards and the dorsum outwards.” This is accounted for by considering the unfavourable conditions in which the long extensor of the toes is placed after paralysis of the interossei. The inferior attachment of this muscle is upon a movable point, the posterior and superior extremities of the second and ungual phalanges. The tendency to extension is counteracted by the interossei, which serve to give a fixed point for the *extensor longus digitorum* to act from, when flexing the foot at the ankle. But when these muscles are paralysed, the attachment of the *extensor longus digitorum* becomes very movable, and we then see at the moment of flexion of the foot upon the leg, that the first phalanges are drawn back even more than before upon the metatarsal bones, at the same time depressing the heads of these bones. The action of the long extensor as a flexor and abductor of the foot is thus much weakened, and this leads to a predominance in the action of the *tibialis anticus* (flexor and adductor of the foot), in consequence of which a mild form of *varus* is produced accompanied by some raising of the heel, due to imperfect flexion of the ankle-joint.

To sum up : this variety of hollow foot (*pied creux*) is produced by an exaggerated and continued action of the extensors of the first phalanges of the

toes—extensor longus digitorum and extensor proprius hallucis—following on a weakness or feebleness of their antagonists, the interossei, adductor, and short flexor of the great toe. Consequently any excess of action of these same extensor muscles, whatever may be its cause, ought to produce exactly identical results.

An obvious objection to Duchenne's theory as to the usual cause of hollow claw-foot is the difficulty of supposing that paralysis should affect solely the interossei and the flexor brevis and adductor hallucis. In some cases there is undoubtedly wasting of other muscles, but this is by no means always the case. Further, although such a localized paralysis may serve to account for the position of the toes, the explanation of the arching of the foot given above seems far from satisfactory.

Perhaps the explanation which on the whole seems the most probable is that suggested by Parkin of Hull, who has endeavoured to prove on mechanical grounds that pes cavus is liable to occur in any case of talipes equinus, "provided only that the patient transmits the weight of the body for a sufficient length of time through the affected foot without the intervention of a raised artificial heel." According to this view the overarching of the foot is explained as follows. Normally the weight of the body is transmitted to the ground in two component parts—through the heel and the ball of the toes, but in cases of equinus the weight is carried by the toes only. If the equinus be extreme, so that the long axis of the foot is brought into a line with the leg, there is no tendency to the production of pes cavus. But, in any case of equinus less severe than this, the weight of the body being transmitted obliquely to the ball of the toes, tends to bring the heel to the ground by a compensatory overarching of the foot, and in this way the heel is made to bear its share of the body-weight. The position of the toes is the result primarily of the old condition of equinus, and secondarily of the displacement of the interossei and the contraction of the extensor muscles.

In some cases a slight degree of pes cavus occurs in patients who have been kept in the recumbent position for long periods. The front part of the foot drops, and the fascial structures of the sole become secondarily shortened.

The *Treatment* of this condition is not satisfactory. The preventive measures should consist in the treatment of any muscular paralysis which may exist, or of talipes equinus, if present. When the deformity is well marked, the position may often be improved by division of the tendo Achillis and the tense bands of plantar fascia. After the operation the foot should be fixed with plaster of Paris or on a rectangular splint. In some cases it may be found advisable to divide also one or more of the extensor tendons of the toes.

**Contraction of One Toe or Hammer Toe**, is not of unfrequent occurrence. In this condition the proximal phalanx is on its normal level or raised up and over-extended; the second phalanx is flexed at an acute angle and cannot be extended, and the third phalanx may be in a line with the second, but is more commonly over-extended. There is always a painful corn over the flexed joint which seriously cripples the patient. The cause of hammer toe is very obscure. It commences almost invariably in youth or childhood, and is occasionally congenital. The deformity is, in some cases, hereditary. It may be aggravated by badly made boots, but does not seem to be primarily caused by them. The second toe is most commonly affected. S. G. Shattock and W. Anderson have shown by dissection that extension is prevented by

shortening of the lateral ligaments chiefly towards the plantar side. The tendons and prolongations of the plantar fascia are normal. In the *treatment* of this condition the toe may sometimes be straightened by subcutaneous division of any resisting structures opposite the head of the second phalanx, but the relief given is often imperfect and seldom permanent. Amputation of the deformed toe has consequently frequently been recommended and performed, but this has the disadvantage of leaving the outer side of the great toe unsupported, and thus giving rise to hallux valgus. Anderson recommends excision of the head of the first phalanx by a longitudinal incision on the lateral aspect of the deformed toe. This leaves the toe straight and completely relieves the deformity.

**Hallux Flexus.**—Under this name a condition was first described by Davies-Colley which is characterized by a contraction of the metatarso-phalangeal, much more rarely of the inter-phalangeal, joint of the great toe. The deformity is analogous to the hammer toe above described. It occurs most commonly in boys, and appears usually to have no relation to injury, or to the wearing of too short boots. In an ordinary case the proximal phalanx is flexed to an angle of from  $30^{\circ}$  to  $60^{\circ}$  and is incapable of extension; the

Fig. 660.—Plantar Aspect.

Fig. 661.—Dorsal Aspect.

Congenital Hypertrophy of Toes and Foot.

distal phalanx is in a straight line with the first. The metatarso-phalangeal joint is often slightly enlarged. The deformity greatly cripples the patient, obliging him to walk on the outer side of the foot. W. Anderson explains the deformity as the result of imperfect development of the lower fibres of the lateral ligaments of the affected joint.

The *treatment* of the slighter forms of hallux flexus should consist in rubbing and manipulation with the object of straightening the toe. Anderson recommends walking on tiptoe as useful in helping extension, and in more severe cases has forcibly over-extended the toe under an anæsthetic, and fixed it so with plaster of Paris. If other methods fail, an attempt may be made to straighten the toe by the division of the contracted ligaments. Davies-Colley has found the most efficient treatment to be excision of the proximal half of the first phalanx through a longitudinal incision made at the upper aspect of the inner border of the toe. A stiff joint results, but this causes little inconvenience.

**Hallux Valgus** has already been described at p. 509.

**Supernumerary and Webbed Toes** are sometimes met with. It is com-

paratively seldom, however, that any operative interference is required in these cases. Should it be, the remarks that have been made at pages 538 and 539, in reference to the treatment of these conditions in the hand, are equally applicable here.

**Congenital Hypertrophy of the Toes and Foot**, as represented in Figs. 660 and 661, occasionally occurs. This malformation is of necessity incurable.

**Weak Ankles** not uncommonly occur in rickety children; the ligaments being relaxed, the joints appearing to be swollen, and the child being unable to walk or stand without great difficulty. In these circumstances, attention to the state of the general health, douching with salt water, with the application of an elastic india-rubber bandage round the ankle, or the use of light iron supports, will be found most useful.

**Bow-Leg** is often associated with weak ankles. The tibia is bent with the concavity looking towards the opposite leg. In some cases the shaft of the bone is curved, but in the majority the bend will be found to be situated at the junction of the lower epiphysis with the shaft, the foot at the same time being turned somewhat out, in the position of valgus. This deformity is in some cases rickety, but in the majority of instances it is purely mechanical, owing to the child, especially if heavy and overfed, having been put on its feet at too early an age or for too long a time.

The **Treatment** consists in careful attention to diet and the avoidance of fattening food, giving the child rest, and in the application of a pair of light well-padded wooden splints to the inner side of the leg, taking their bearing-points from the inner condyle of the femur and the inner malleolus. These should be worn only at night.

## DISEASES OF REGIONS.

## CHAPTER LIV.

## DISEASES OF THE HEAD AND NECK.

## DISEASES OF THE SCALP AND SKULL.

**The Scalp** is subject to all those surgical diseases that affect the common integument of the body. But it is more than any other part of the surface liable to two diseases, viz., Atheromatous Cysts and Nævi. These have already been so fully treated of (Cysts, Vol. I., p. 1006, Nævi, Vol. I., p. 1028, and Vol. II., p. 69) that their description here would lead to needless repetition.

**Pachydermatous Tumour of the Scalp or Molluscum Fibrosum** (Vol. I., p. 1019). This disease, of rare occurrence, was first described by

John Bell, subsequently by Valentine Mott as *Pachydermatocoele*, and more recently by Virchow as *Fibroma Molluscum*. The accompanying cut (Fig. 662), taken from a patient whilst in America, who was afterwards successfully operated on by W. Stokes, in Dublin, gives a good representation of the disease.

These tumours are neither painful nor dangerous, but their weight and the deformity occasioned by them render their removal desirable.

*Treatment.*—The removal of this tumour has been effected by the ligature and by the knife. Pollock has successfully extirpated one by the former, W. Stokes and others by the latter method. But the operation is not without danger. In

Fig. 662.—Molluscum Fibrosum of Scalp.

Stokes's case the hæmorrhage was described as terrific, nearly costing the patient his life, and had to be arrested by the cautery. Stokes states that in the whole course of his experience he had never seen such copious and uncontrollable "weeping" hæmorrhage; it came from every point of the cut surface.

**Fungus of the Dura Mater.**—Sometimes without apparent cause, at other times following a blow or fall, a *Fungous Tumour* grows from some part of the dura mater, usually on the top of the head or in one of the parietal

regions. As it increases in size, it produces absorption of the skull covering it; the bone becomes thin and expanded, and crackles like parchment on pressure, sometimes not being raised above its proper level, but usually being pushed up by the pressure of the growth beneath, which at last protrudes under the scalp, and may ulcerate through the skin. More usually, this perforation of the skull is gradual; but in some cases it would appear to have been rapid, the first sign of the disease being the presence of a tumour under the scalp. When the skull is perforated, the sharp edges of the circular opening can be distinctly felt, and the protruding tumour pulsates distinctly.

*Pathology.*—The nature of these tumours is somewhat uncertain, as a sufficient number of cases has not yet been recorded with an accurate microscopical description of the growth; but it is probable that in the majority of cases they are round- or spindle-celled sarcomata springing from the outer layers of the membrane, which forms the internal periosteum of the skull.

*Symptoms.*—Symptoms of cerebral disturbance—diplopia, optic neuritis, loss of sight, deafness, or convulsions, with fixed pain in the head—usually precede for a considerable time the external appearance of the tumour. In some rare cases, no such symptoms have indicated the existence of intracranial disease; and the first evidence of the disease has been the sudden protrusion of a pulsating tumour through the skull. If the tumour be compressed, egg-shell crackling of the expanded and thinned cranial bones will be felt, and, if attempts be made to push it back under the bones, giddiness, syncope, and convulsions are produced. As the disease progresses, death from paralysis and coma supervenes.

*Treatment.*—The result of the treatment of fungus of the dura mater is not very satisfactory; yet, as the disease appears to be almost of necessity fatal if left to itself, something should be attempted if possible. The scalp covering it should be turned back by suitable incisions, and the tumour exposed. The aperture in the skull through which it protrudes may then, if necessary, be enlarged by the use of the trephine or Hey's saw, so as to lay bare the full extent of the tumour, which must next be carefully dissected away from the dura mater, or the affected part of the latter removed. In a case in which this operation was performed by Volkmann, the patient died from the entrance of air during inspiration through an accidental wound of the longitudinal sinus.

**Fungus of the Skull** may also occur. This term has been applied to any soft fungating tumour springing primarily from the vault of the skull. The growth may spring from beneath the periosteum, when it is usually a small round-celled or a spindle-celled sarcoma, or from the diploë, when it is most commonly myeloid. It gives rise to a smooth ovoid tumour on the head, which may or may not pulsate. If it springs from the diploë it is usually covered by a thin layer of bone, which gives the sensation of egg-shell crackling; when it is subperiosteal, it not uncommonly contains a framework of irregular spicula of bone. As the disease progresses it usually perforates the skull, and comes into contact with the dura mater. It is then very difficult to determine whether it arose from that membrane, or merely implicated it by extension. The growth may, when small, be mistaken for an atheromatous cyst of the scalp, but it is readily distinguished by its being firmly fixed to the bone, while the cyst moves with the scalp. These tumours may become multiple, and after a time be followed by secondary visceral growths. I have

twice seen the liver secondarily affected in this way, death resulting without cerebral disturbance from intestinal hæmorrhage and exhaustion. The only *treatment* possible is removal of the growth, but this is accompanied by considerable danger, not only on account of the perforation of the skull and implication of the dura mater, but from the extreme vascularity of these tumours. In a case of this kind, which I had an opportunity of seeing many years ago, the growth was successfully removed by B. Phillips.

Secondary sarcomata and carcinomata are also occasionally met with in the bones of the skull. In a case recorded by Morris, a large pulsating tumour of the skull was found to present the structure of the thyroid gland, and was secondary to malignant disease of that body. Three or four similar cases have been recorded by other Surgeons.

**Hernia Cerebri**, arising from wound or ulceration of the dura mater, has already been described (Vol. I., p. 778).

**Meningocele** and **Encephalocele**.—Various congenital conditions are met with in the head, which as in the analogous condition of spina bifida, are characterized by a protrusion of some part of the contents of the skull through a deficiency in the bone. The protruded sac is formed by the meninges; the skin covering may be normal, but is often thin, and sometimes ulcerated. When the contents of the sac consist of fluid only the condition is spoken of as *meningocele*; whilst when the sac contains cerebral substance it is called an *encephalocele*. In some instances the brain substance in the sac is distended into a thin layer by a cavity within it which contains fluid and communicates with the ventricles; this variety has been called *hydrencephalocele*. The diagnosis between meningocele and encephalocele is generally difficult; the presence of translucency is not a proof that no brain substance is present, for this may be small in amount or expanded into a thin layer.

The disease is usually speedily fatal. Z. Laurence found that, of 39 instances in which it occurred, 21 were males, 18 females; that the protrusion may vary from the size of a pea to that of a tumour exceeding the child's head; and that the occiput is its chief seat—of 79 cases, 53 being in this situation. The hernia may occur at several other points. It has been seen projecting through the anterior fontanelle. In this situation it has most frequently undergone spontaneous cure as the fontanelle closed. Numerous cases have been recorded in which it projected through a deficiency in the region of the cribriform plate into the nasal fossæ, or forwards into the face at the root of the nose, the nasal process and the neighbouring parts of the frontal bone being deficient. Lichtenberg has recorded a case in which it projected from the base of the skull into the pharynx. In these uncommon situations, the swelling may be mistaken for a polypus. In six of the cases collected by Z. Laurence, the subjects of this malformation reached an adult age; in all the remaining cases they died early, or were still-born.

The *Diagnosis* is as a rule easy, and the only diseases for which a meningocele is likely to be mistaken are nævi and dermoid cysts. In the majority of cases the position of these tumours is such as to exclude meningocele, but if they occur in the usual positions of meningocele the resemblance may be close, and is increased by the fact that the skin over a meningocele is not uncommonly navoid, and on the other hand dermoid cysts of the scalp often lie over a depression or even a perforation in the bone.

The *Treatment* of these affections is unsatisfactory, and in most cases no

surgical interference should be attempted. Pressure may be applied if the tumour is small. In one instance Paget used injection of iodine with success. In another case, where sloughing of a portion of the tumour was taking place, Annandale applied a ligature to the peduncle, and removed the tumour, the child recovering completely in spite of an attack of measles. Horsley has recorded a case which he cured by electrolysis. Simple meningoceles have been successfully excised, and in recent years the operation has been extended, in several cases with success, to encephalocele.

**Tapping and Draining the Ventricles of the Brain.**--The operation of tapping the ventricles has occasionally been performed in chronic hydrocephalus, but so far without much benefit. It is sometimes conjoined with pressure by means of an elastic bandage. It is applicable only to those cases in which, from the early age of the child, or the imperfect ossification of the distended skull, it is possible to compress the head by a moderate degree of pressure. The operation is best performed by means of the aspirator. A fine needle may be pushed through the anterior fontanelle or the coronal suture, avoiding the middle line for fear of wounding the longitudinal sinus. The instrument should be directed away from the middle line so as to penetrate the lateral ventricle, and thus to evacuate a portion of the contained fluid. There should be no vacuum in the needle when it is introduced, but when it has penetrated deeply enough to reach the ventricle, the piston of the aspirator may be slowly raised, so as to withdraw the fluid gradually, and not to disturb the circulation through the brain. After a moderate quantity of fluid has been withdrawn, the small aperture should be closed with a strip of plaster, and an elastic bandage should be applied round the head so as to compress and to confine the bones.

In 1881 Wernicke suggested that in cases of hydrocephalus better results might be obtained by draining the lateral ventricles by a tube introduced through a trephine opening. This suggestion has been put into practice by Keen, Broca, Mayo Robson, and others. In Keen's first case, a boy four years of age, the hydrocephalus proved to be secondary to a tumour of the cerebellum. The trephine was applied at a point an inch and a quarter above, and the same distance behind the left external auditory meatus; the ventricle was reached with a hollow needle and a horse-hair drain inserted. Subsequently the operation was repeated on the opposite side. Death occurred on the forty-fifth day, and the autopsy revealed a sarcomatous tumour in the cerebellum. In Broca's case, a hydrocephalic idiot aged four years, the operation was followed by recovery with considerable improvement in the mental condition.

In cases in which hydrocephalus develops after the occurrence of symptoms of basic meningitis, attempts have been made to relieve the condition by draining the subarachnoid space in the occipital region—either in the middle line between the external occipital protuberance and the foramen magnum or through the cerebellar fossa. The results, however, appear to have been uniformly unfavourable.

Lastly, it may be mentioned that during the last few years several attempts have been made to bring tuberculous meningitis within the range of surgical interference. The hope has indeed been expressed that by applying drainage to these cases, not only might the immediate effects of the increased intracranial pressure be relieved, but also that the disease might be arrested in a

manner analogous to that which has followed drainage for tuberculous peritonitis. A case recorded by Waterhouse and Wallis Ord is certainly hopeful. A child aged five years was the subject of an acute illness characterized by fever, headache, double optic neuritis, and the characteristic "hydrocephalic cry." The diagnosis of tuberculous meningitis was made, and it was decided to drain the subarachnoid space through a trephine opening in the cerebellar fossa. The operation was followed by complete recovery and subsidence of the optic neuritis.

**Operations on the Brain.**—Since the clinical and pathological observations and the experimental inquiries of Broca, Hughlings Jackson, Hitzig, Ferrier and others, have made it possible to diagnose the exact seat of many tumours and other lesions within the cranium, and the development of antiseptic surgery has enabled the Surgeon to operate on the brain substance with comparative safety, many such procedures have been undertaken. The general subject of localisation of the functions of the brain has already been sufficiently alluded to in the Chapter on Injuries of the Head (Vol. I., p. 753). The special symptoms of the diseases for which the operations have been undertaken belong rather to medicine than surgery, and cannot be fully described here.

Operations upon the brain have been undertaken for the removal of morbid growths, for the relief of epilepsy, and for abscess of the brain.

*Morbid growths of the brain* are either syphilitic or tuberculous, or true tumours, the most frequent form of true tumour being the glioma (Vol. I., p. 1037). Sarcomata of various kinds are occasionally met with. True cancer is rare, and only occurs as a secondary growth. Psammoma of the dura mater (Vol. I., p. 1045) may also cause pressure on the brain. All the tumours except the psammoma as a rule implicate the surrounding brain tissue, being seldom accurately circumscribed. The genera symptoms of an intracranial tumour may be briefly summarised as signs of irritation or impaired function in that part of the brain in which the new growth is situated, with fixed and persistent headache. Vomiting is a common symptom, and optic neuritis is almost constantly present when the tumour is situated in the substance of the brain. When the growth affects the cortical centres epileptiform seizures are common, and the fit commences by spasm of the part in connexion with the centre implicated. In considering the possibility of removal of a tumour of the brain the situation of the growth is of the first importance. It must be so seated that it can safely be exposed by trephining the skull. Tumours at the base, or deeply seated in the brain, are evidently beyond surgical interference. If the paralysis is very extensive the growth is implicating so wide an area that its removal probably could not be accomplished or would speedily be followed by recurrence. The nature of the tumour must in many cases be uncertain, but, if it can be ascertained, has an important influence on the question of operation. Tuberculous growths are often multiple, and thus unsuitable for operation; if, however, the symptoms point to the tumour being single, its removal may be attempted. In 1886 Horsley removed a tuberculous tumour successfully; the child died six years later of genito-urinary tuberculosis, and the brain was found quite sound. Syphilitic gumata frequently disappear under proper treatment, but not necessarily the symptoms, which may be due to chronic inflammatory changes around the growth. In all cases of doubtful nature a thorough trial should be given to

antisypilitic treatment for at least six weeks before operation is undertaken. A true tumour is generally characterized by a slow progressive development of the symptoms, while both tuberculous and syphilitic growths may after a time become stationary. The cases suited to operation are undoubtedly rare. Of 54 specimens of intracranial tumour reported on by a committee of the Pathological Society in 1886 only two seemed suited to operation.

Trephining for *epilepsy* has frequently been undertaken as before described (Vol. I., p. 780) in cases of traumatic origin, and in which there has been a painful or tender scar, or some evident depression of the bone; but it is only within the last few years that portions of the brain have been removed for the cure of that disease. To justify the operation it is necessary that every fit must commence with some definite movement which can be referred to one of the cortical motor centres, or that there should be some paresis or paralysis indicating the part of the cortex affected, without which there can be no guide as to the point at which to apply the trephine.

Trephining for *abscess of the brain* consequent upon compound fractures of the skull or scalp wounds exposing the bone has long been a recognised operation of surgery. It is but recently, however, that the operation has been undertaken for abscess resulting from disease of the ear, with which condition it will be more fully described.

The first operation undertaken for the relief of symptoms due to a morbid growth in the brain was performed by Macewen in 1883. The patient had paralysis of the left arm, and a softening gumma was exposed by trephining over the arm centre of the right side. The patient recovered.

The first operation for a diagnosed glioma was performed by Godlee in a case under the care of Hughes Bennett in 1884. The patient unfortunately died about a month after the operation from hernia cerebri and meningitis. Since that time the operation has been brought to great perfection by Victor Horsley. Of the first four cases treated by him three recovered, one dying subsequently of recurrence. The fourth case was one of tumour of the cerebellum, and the patient died from the shock of the operation.

Writing in 1893, Allen Starr was able to collect 97 cases in which operations had been undertaken for diagnosed tumour of the brain, in 35 of which however the tumour was not found, while in 3 it was found but not removed. There thus remain 59 cases in which the tumour was successfully localized and removed; of these 42 recovered and 17 died. Concerning the position of the tumour it may be stated that in 54 cases this was one of the cerebral hemispheres, 43 being in the motor area. Of these 54 cases of cerebral tumour 39 recovered and 15 died. In the remaining 5 cases a tumour was removed from the cerebellum; of these 2 recovered and 3 died.

In certain cases of cerebral tumour in which the position or size of the growth renders its removal impossible, Horsley has undertaken a free excision of bone over it with the object of relieving the symptoms directly due to increased intracranial pressure. The relief thus afforded has in some instances been very marked, and has persisted until the patient's death. Thus the headache may entirely cease, whilst in cases with severe vomiting this has at once stopped. The most remarkable result, however, is the effect upon the optic neuritis; if this has not advanced to atrophy the swelling of the disc rapidly begins to diminish, and in some instances the neuritis has completely subsided within three weeks.

*Operation.*—The operation of trephining has already been described in Vol. I., p. 782, so that it will be necessary here only to mention certain points more especially connected with the removal of tumours. Immediately before the administration of the chloroform a quarter of a grain of morphine should be injected hypodermically, as suggested by Schäfer and Horsley, with the object of causing contraction of the arterioles of the brain, and thus diminishing the hæmorrhage. Ether must never be used as the anæsthetic for fear of producing hæmorrhage. The large flap of the scalp, which is turned downwards without the periosteum, should extend in every direction for more than an inch beyond the limits of the bone to be removed. The vessels are quickly seized in force-pressure forceps and ligatured with fine silk. The general oozing is arrested by sponge pressure, and by frequently irrigating the wound with hot mercurial lotion (1 in 4000). The periosteum is now raised with an elevator in four flaps. The bone may conveniently be divided with an electro-motor circular saw, or a circle of bone may be removed with a trephine, and the opening enlarged with Horsley's strong bone-forceps. In order to facilitate this it may be convenient to make diagonal cuts through the outer table with a Hey's saw before trephining. Before using the bone-forceps the dura mater must be separated with a small flat elevator. Hæmorrhage from the bone may be arrested with the antiseptic wax recommended by Horsley (bees' wax 7 parts, almond oil 1 part, salicylic acid 1 per cent.). The dura mater is raised by incising it at a distance of at least a quarter of an inch from the edges of the opening in the bone. Before proceeding to remove any portion of the brain substance, it is advisable to apply a series of fine catgut ligatures to the surrounding veins, by passing a sharp curved needle under them through the brain substance. These ligatures must be applied well beyond the area to be excised. The latter should be marked out by incising the cortex to a depth of about half an inch with a scalpel, and the removal may be completed with the knife or with curved scissors. Any vessels which bleed may be secured by passing a fine ligature somewhat widely around them with a curved needle. The method of treating the wound, and the question of the replacement of bone, have already been considered in Vol. I., p. 784. During the operation the pulse and respiration must be carefully watched, and if either fail the skull should be opened as rapidly as possible, so that the intracranial pressure may be relieved.

**Craniectomy.**—In certain cases of idiocy the imperfect development of the mental faculties is associated with a condition of microcephalus due to premature ossification of the cranial sutures, especially the coronal and sagittal. The occurrence of this synostosis necessarily interferes with the further development of the brain, and is regarded by some pathologists as the primary condition. The operation of craniectomy has for its object the formation of an artificial suture by the removal of a narrow strip of bone from the vertex of the skull, in order to allow subsequent continued development of the brain. In 1890 Lannelongue recorded two cases in which considerable improvement appears to have followed the operation. The first case was a child 4 years of age, which presented the characteristic condition of the skull, and was unable to walk alone, talk plainly, or swallow solid food. A strip of bone, 9 centimetres long and 6 millimetres wide was removed from a little to the left of the sagittal suture. The habit of incessant crying ceased on the following day, and in five weeks "the child was calmer, tried to talk, and took notice of its

surroundings." The operation has been performed in 25 cases by Lannelongue and by Horsley, Keen, McClintock, and others. Of 88 cases collected by Bourneville in 1893, 15 died.

Of Lannelongue's 25 cases 24 recovered; the ages varied from eight months to twelve and a half years; the greater number showed evident improvement after the operation. In most cases the strip of bone has been removed from the left side, but in some a second strip has been removed from the right. The bone is exposed by a long antero-posterior incision reaching from the neighbourhood of the frontal eminence a varying distance backwards and an inch from the middle line; the incision may be slightly curved, so that a flap can be reflected. A strip of periosteum corresponding to the bone to be removed is next cut away, and the bone itself, in a strip 4 to 6 inches long and half an inch broad, is removed with Hofmann's or other bone forceps after cutting out a small circle of bone with the trephine. In one of Horsley's cases a second strip was removed transversely over the coronal suture in the hope of relieving the speech-centre. The operation is not without danger in young children, and two cases at least have died of hyperpyrexia, not caused by septic processes in the wound, but probably due to disturbance of the heat regulating centres in the cortex. Even at some risk to life the operation is fully justified if it holds out even a small hope of improvement in these distressing cases, and certainly the results so far recorded seem to warrant its further trial.

#### DISEASES OF THE EAR.

**Method of Examination.**—In order to ascertain the patient's power of hearing, a watch or tuning-fork is most commonly used, and separate estimations must be made of the power of appreciating sounds conducted through the air and through the bones of the skull. In this way the cases of deafness due to some obstruction of the conducting apparatus can readily be distinguished from those in which the essential part of the organ of hearing is at fault. In the former case all power of appreciating sounds conducted through the air may be lost, whilst sounds transmitted directly to the auditory apparatus through the bone are still distinctly audible; in the latter case the power of hearing is diminished or lost to both paths of conduction.

The degree of hearing through the air may be roughly estimated by comparing the maximum distance from the ear at which the ticking of a watch is heard by the patient as compared with that of a person with normal hearing power. The patient's eyes should be closed, and a finger placed over the opposite ear; the watch is then brought slowly nearer to the ear under examination until its sound is first heard, and the distance noted.

In order to determine the power of hearing through the bone, a vibrating tuning-fork is firmly held against the upper part of the mastoid process. If with an ear deaf to sound through the air the tuning-fork is now heard, it is certain that the conducting channels, and not the auditory apparatus itself, are at fault. If the vibrating tuning-fork be pressed against the vertex, in health it is heard equally in the two ears; if, however, one meatus or one Eustachian tube be blocked, the sound will be heard more loudly in the affected ear.

For examining the membrana tympani or tympanum from the meatus, the ordinary silver ear speculum will be found as efficient as any of the more

complicated instruments sometimes recommended. The light must be thrown down it by a concave mirror similar to that used for the laryngoscope. If necessary, the ear must first be carefully cleaned by syringing and afterwards dried by means of small pieces of absorbent wool twisted round the end of a bit of whalebone or wood. The membrane in health is of a bluish-grey colour, and the handle of the malleus can be seen crossing it from above downwards and slightly backwards, terminating a little beyond its middle. The membrane is set at an angle of 45 degrees with the floor of the meatus; but owing to its concavity looking outwards, a small triangular part below and slightly in front of the end of the handle of the malleus reflects back the light to the eye of the observer, and thus appears as a bright spot. The points to be observed in examining the membrane are its degree of opacity, its colour, and degree of vascularity; its curvature, whether too concave, or convex and bulging; and the presence or absence of perforation.

The instrument known as *Politzer's bag* is of great value in examining the condition of the Eustachian tube and the middle ear. It consists of a thick india-rubber bag with a blunt nozzle, and is used thus: The nozzle is inserted into one nostril, and both nostrils are then squeezed between the finger and thumb, so as efficiently to close the anterior nares; the patient then takes a small quantity of water into the mouth and holds it till directed to swallow; at the moment he swallows, the bag is squeezed, and the upper part of the pharynx above the soft palate is thus distended with air, and as at the same time the Eustachian tubes are opened by the act of swallowing, the air rushes into the cavity of the tympanum. While this is being done the Surgeon connects his ear with that of the patient by means of an india-rubber tube about three feet in length with an ear-piece at each end. He thus hears distinctly the effect produced by the distension of the cavity of the tympanum. The cavity of the tympanum can usually be distended equally well by Valsalva's method, in which the patient closes the mouth and pinches the nostrils, and then makes a forced effort of expiration. The following are the chief facts learned from this mode of investigation. In health, the Surgeon hears the air enter the tympanum and impinge on the membrane with a sharp click, sounding to the patient as a loud crack. If the Eustachian tube is closed by swelling or plugged with inspissated pus or mucus also filling the tympanum, this will be entirely wanting. If the cavity is filled with tenacious mucus or muco-purulent fluid, a crackling bubbling sound will be heard both by the Surgeon and the patient as the air enters the cavity. If the membrane is perforated and the Eustachian tube pervious, the air will be heard passing through the aperture.

The *Eustachian Catheter* is useful in treatment rather than in diagnosis. It consists of a small metal or vulcanite tube about six inches in length with a slight curve at one end and expanded at the other to receive the nozzle of the small india-rubber bag used for injecting fluid or air. On the large end is a ring to show the position of the point while it is in the nose. It is thus passed: The concavity of the curve being turned towards the floor of the nasal fossa, so that the point may not hitch against the turbinate bones, the catheter is passed backwards through the nose till it touches the posterior wall of the pharynx. It is then withdrawn about half an inch and its point directed outwards and slightly upwards against the orifice of the Eustachian tube. The Surgeon having his ear connected with that of the patient by the india-rubber

tube before described, can then ascertain whether the catheter is in the tube or not by blowing some air through it from a small india-rubber bag.

**AFFECTIONS OF THE EXTERNAL EAR AND MEATUS.**—**Malformations** of the lobule are not uncommon. Absence of the pinna or such deformity as completely to close the meatus has also been met with. **Hypertrophy** of the external ear is sometimes met with in idiots ; and in gouty subjects, **Tophi**, or **Gouty Concretions**, are occasionally deposited in it. Paget, Bruck, and Vanzetti have described a **Fibrous Tumour** that occasionally forms in the lobule of the ear from the irritation produced by piercing it, as “one of the penalties attached to the barbarism of ear-rings.” These tumours are semi-malignant, like the warty growths of cicatrices ; and, after excision—the only treatment—are somewhat apt to return.

**Bloody Tumours**, or **Hæmatomata**, are occasionally developed without apparent cause in the external ear of the insane or idiots, and are not uncommon in other patients as the result of injury. They may attain a large size, and are often multiple. Unless they become inflamed, I think it better to leave them untouched, when they will gradually be absorbed. If inflamed, they must be opened.

**Eczema of the External Ear**, sometimes extending into the external meatus, is a common affection. It occurs in scrofulous children and in gouty adults. The constitutional treatment must be conducted on ordinary principles ; locally the application of glycerine of borax or of boric acid ointment, to which a small quantity of extract of belladonna may be added, will be found most useful.

**Concretions in the Meatus.**—We not uncommonly find that the meatus becomes blocked up by accumulations of wax, dark, indurated, and pipe-like, or forming balls and masses that lie in contact with the membrana tympani. These are a very common source of temporary deafness among young people. They not only materially impair the sense of hearing, but are very apt to give rise to noises in the head, and to crackling sensations on opening and shutting the mouth. Their presence is best ascertained by examination with an ear-speculum. The *Treatment* of these concretions consists in softening the wax by the introduction of a little glycerine into the ear for a few nights, and then repeatedly washing out the meatus by the injection of tepid soap and water, thrown in with a large syringe ; as the fluid regurgitates from the membrana tympani, it will at length bring away dark and hardened ceruminous masses.

**Thickening of the Cuticle.**—Occasionally the cuticle of the external meatus, and that covering the membrana tympani, becomes thickened and indurated, assuming a dull white appearance. This is commonly a result of eczema, and may give rise to some degree of deafness. In these circumstances, glycerine, citrine ointment, or solution of nitrate of silver, will be useful in restoring the healthy condition of the part.

**Boils or Follicular Abscesses** are not uncommon in the external meatus. They may arise as a complication of eczema, or as the consequence of irritating discharges from the middle ear. The *Treatment* is to apply hot fomentations to the ear, and, if the boil can be seen, relief may often be given by puncturing it with a small knife.

**Diffuse Inflammation of the Meatus** or **Otitis Externa** is most common in children, and may occur from a variety of causes, amongst which

are measles and scarlet fever, eczema or injuries. In some cases the inflammation affects the periosteum, and in all, unless it be checked early, it tends to implicate the membrana tympani. The symptoms are redness and swelling, more or less completely closing the auditory canal, with intense pain, aggravated in many cases by any movement of the jaw. After a time a purulent discharge escapes, when some relief usually follows. The disease may assume a chronic form with discharge from the ear, forming one of the varieties of otorrhœa. In other cases **abscess** forms which may lead to disease of the bony walls of the canal. In some cases the canal becomes closed by the swelling, and perforation of the membrana tympani may take place. The *Treatment* in the early stages consists of leeches behind the ear, followed by hot fomentations. If suppuration threatens, the pus must be let out early by a free incision made deeply to the bone with a fine knife passed into the meatus.

**Exostoses.**—Small exostoses occasionally form in the ear, springing from the bony part of the external meatus. These may cause deafness by completely obstructing the canal. They have been successfully treated by Mathewson of New York, Field, Dalby, and others by means of the American dental drill.

**Periosteal Thickenings**, the result of syphilis, are occasionally met with. These usually disappear under iodide of potassium.

**DISEASES OF THE MIDDLE EAR.**—It is impossible in a work of this kind to give more than the briefest possible description of the affections to which the middle ear is liable; for fuller information the student must refer to special works.

The diseases of the middle ear are commonly classed under the following headings: Simple Mucous Catarrh and Purulent Catarrh, and each of these is divided into acute and chronic.
